The video coder may comprise a video encoder. It may comprise a video decoder. There may be a codec comprising both the video encoder and the video decoder.

According to a fifth aspect of the invention, there is provided a communications terminal comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the video coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $1/2^x$, where x is a positive integer having a maximum value N , the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical locations directly using a choice of a first weighted sum of values for sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and a second weighted sum of values for sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations, the first and second weighted sums of values being calculated according to step (a); and
- c) interpolate a value for a sub-pixel situated at a $1/2^N$ unit horizontal and $1/2^N$ unit vertical location by taking a weighted average of the value of a first sub-pixel or pixel situated at a $1/2^{N-m}$ unit horizontal and $1/2^{N-n}$ unit vertical location and the value of a second sub-pixel or pixel located at a $1/2^{N-p}$ unit horizontal and $1/2^{N-q}$ unit vertical location, variables m , n , p and q taking integer values in the range 1 to N such that the first and second sub-pixels or pixels are located diagonally with respect to the sub-pixel at $1/2^N$ unit horizontal and $1/2^N$ vertical location.

The communications terminal may comprise a video encoder. It may comprise a video decoder. Preferably, it comprises a video codec comprising a video encoder and a video decoder.

Preferably the communications terminal comprising a user interface, a processor and at least one of a transmitting block and a receiving block, and a video coder according to at least one of the third and fourth aspects of the invention. Preferably the processor controls the operation of the transmitting block and/or the receiving block and the video coder.

According to a sixth aspect of the invention, there is provided a telecommunications system comprising a communications terminal and a network, the telecommunications network and the communications terminal being connected by a communications link over which coded video can be transmitted, the communications terminal comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the video coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $1/2^x$, where x is a positive integer having a maximum value N , the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$

unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;

- b) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical locations directly using a choice of a first weighted sum of values for sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and a second weighted sum of values for sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations, the first and second weighted sums of values being calculated according to step (a); and
- c) interpolate a value for a sub-pixel situated at a $1/2^N$ unit horizontal and $1/2^N$ unit vertical location by taking a weighted average of the value of a first sub-pixel or pixel situated at a $1/2^{N-m}$ unit horizontal and $1/2^{N-n}$ unit vertical location and the value of a second sub-pixel or pixel located at a $1/2^{N-p}$ unit horizontal and $1/2^{N-q}$ unit vertical location, variables m, n, p and q taking integer values in the range 1 to N such that the first and second sub-pixels or pixels are located diagonally with respect to the sub-pixel at $1/2^N$ unit horizontal and $1/2^N$ unit vertical location.

Preferably the telecommunications system is a mobile telecommunications system comprising a mobile communications terminal and a wireless network, the connection between the mobile communications terminal and the wireless network being formed by a radio link. Preferably the network enables the communications terminal to communicate with other communications terminals connected to the network over communications links between the other communications terminals and the network.

According to a seventh aspect of the invention, there is provided a telecommunications system comprising a communications terminal and a network, the telecommunications network and the communications terminal being connected by a communications link over which coded video can be transmitted, the network comprising a video coder for coding for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the video coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $1/2^x$, where x is a positive integer having a maximum value N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical locations directly using a choice of a first weighted sum of values for sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and a second weighted sum of values for sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations, the first and second weighted sums of values being calculated according to step (a); and
- c) interpolate a value for a sub-pixel situated at a $1/2^N$ unit horizontal and $1/2^N$ unit vertical location by taking a weighted average of the value of a first sub-pixel or pixel situated at a $1/2^{N-m}$ unit horizontal and $1/2^{N-n}$ unit vertical location and the value of a second sub-pixel or pixel located at a $1/2^{N-p}$ unit horizontal and $1/2^{N-q}$ unit vertical location, variables m, n, p and q taking integer values in the range 1 to N such that the first and second sub-pixels

or pixels are located diagonally with respect to the sub-pixel at $1/2^N$ unit horizontal and $1/2^N$ unit vertical location.

According to an eighth aspect of the invention there is provided a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the resolution of the sub-pixels being determined by a positive integer N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

The interpolator may be further adapted to form the first weighted sum using the values of sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and to use the first weighted sum to interpolate a value for a sub-pixel at $1/2^{N-1}$ unit horizontal and $1/2^N$ unit vertical location.

The interpolator may be further adapted to form the second weighted sum using the values of sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations and to use the second weighted sum to interpolate a value for a sub-pixel at $1/2^N$ unit horizontal and $1/2^{N-1}$ unit vertical location.

The interpolator may be further adapted to interpolate values for sub-pixels at $1/2^N$ unit horizontal and $1/2^N$ unit vertical locations by taking the average of at least one pair of a first pair of values of a sub-pixel located at a $1/2^{N-1}$ unit horizontal and unit vertical location, and a sub-pixel located at a unit horizontal and $1/2^{N-1}$ unit vertical location and a second pair of values of a pixel located at a unit horizontal and unit vertical location, and a sub-pixel located at a $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical location.

According to a ninth aspect of the invention there is provided a communications terminal comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the resolution of the sub-pixels being determined by a positive integer N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

21

According to a tenth aspect of the invention there is provided a telecommunications system comprising a communications terminal and a network, the telecommunications network and the communications terminal being connected by a communications link over which coded video can be transmitted, the communications terminal comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the resolution of the sub-pixels being determined by a positive integer N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

According to an eleventh aspect of the invention there is provided a telecommunications system comprising a communications terminal and a network, the telecommunications network and the communications terminal being connected by a communications link over which coded video can be transmitted, the network comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the resolution of the sub-pixels being determined by a positive integer N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

BRIEF DESCRIPTION OF THE FIGURES

An embodiment of the invention will now be described by way of example only with reference to the accompanying drawings in which:

FIG. 1 shows a video encoder according to the prior art;

FIG. 2 shows a video decoder according to the prior art;

FIG. 3 shows the types of frames used in video encoding;

FIGS. 4a, 4b, and 4c show steps in block-matching;

FIG. 5 illustrates the process of motion estimation to sub-pixel resolution;

22

FIG. 6 shows a terminal device comprising video encoding and decoding equipment in which the method of the invention may be implemented;

FIG. 7 shows a video encoder according an embodiment of the present invention;

FIG. 8 shows a video decoder according to an embodiment of the present invention;

FIG. 11 shows a schematic diagram of a mobile telecommunications network according to an embodiment of the present invention;

FIG. 12a shows a notation for describing pixel and sub-pixel locations specific to TML5;

FIG. 12b shows interpolation of a half resolution sub-pixels;

FIG. 12c shows interpolation of a half resolution sub-pixels;

FIG. 13a shows a notation for describing pixel and sub-pixel locations specific to TML6;

FIG. 13b shows interpolation of a half resolution sub-pixels;

FIG. 13c shows interpolation of a half resolution sub-pixels;

FIG. 14a shows a notation for describing pixel and sub-pixel locations specific to the invention;

FIG. 14b shows interpolation of a half resolution sub-pixels according to the invention;

FIG. 14c shows interpolation of a half resolution sub-pixels according to the invention;

FIG. 15 shows possible choices of diagonal interpolation for sub-pixels;

FIG. 16 shows the half resolution sub-pixel values required to calculate other half resolution sub-pixel values;

FIG. 17a shows the half resolution sub-pixel values that must be calculated in order to interpolate values for quarter resolution sub-pixels in an image block using the interpolation method of TML5;

FIG. 17b shows the half resolution sub-pixel values that must be calculated in order to interpolate values for quarter resolution sub-pixels in an image block using the interpolation method according to the invention;

FIG. 18a shows the numbers of half resolution sub-pixels that must be calculated in order to obtain values for quarter resolution sub-pixels within an image block using the sub-pixel value interpolation method according to TML5;

FIG. 18b shows the numbers of half resolution sub-pixels that must be calculated in order to obtain values for quarter resolution sub-pixels within an image block using the sub-pixel value interpolation method according to the invention;

FIG. 19 shows a numbering scheme for each of the 15 sub-pixel positions;

FIG. 20 shows nomenclature used to describe pixels, half resolution sub-pixels, quarter resolution sub-pixels and eighth resolution sub-pixels

FIG. 21a shows the diagonal direction to be used in the interpolation of each eighth resolution sub-pixel in an embodiment of the invention;

FIG. 21b shows the diagonal direction to be used in the interpolation of each eighth resolution sub-pixel in another embodiment of the invention; and

FIG. 22 shows nomenclature used to describe eighth resolution sub-pixels within an image.

DETAILED DESCRIPTION

FIGS. 1 to 5, 12a, 12b, 12c, 13a, 13b, and 13c have been described in the foregoing.

FIG. 6 presents a terminal device comprising video encoding and decoding equipment which may be adapted to operate in accordance with the present invention. More precisely, the figure illustrates a multimedia terminal **60** implemented according to ITU-T recommendation H.324. The terminal can be regarded as a multimedia transceiver device. It includes elements that capture, encode and multiplex multimedia data streams for transmission via a communications network, as well as elements that receive, de-multiplex, decode and display received multimedia content. ITU-T recommendation H.324 defines the overall operation of the terminal and refers to other recommendations that govern the operation of its various constituent parts. This kind of multimedia terminal can be used in real-time applications such as conversational videotelephony, or non real-time applications such as the retrieval/streaming of video clips, for example from a multimedia content server in the Internet.

In the context of the present invention, it should be appreciated that the H.324 terminal shown in FIG. 6 is only one of a number of alternative multimedia terminal implementations suited to application of the inventive method. It should also be noted that a number of alternatives exist relating to the location and implementation of the terminal equipment. As illustrated in FIG. 6, the multimedia terminal may be located in communications equipment connected to a fixed line telephone network such as an analogue PSTN (Public Switched Telephone Network). In this case the multimedia terminal is equipped with a modem **71**, compliant with ITU-T recommendations V.8, V.34 and optionally V.8bis. Alternatively, the multimedia terminal may be connected to an external modem. The modem enables conversion of the multiplexed digital data and control signals produced by the multimedia terminal into an analogue form suitable for transmission over the PSTN. It further enables the multimedia terminal to receive data and control signals in analogue form from the PSTN and to convert them into a digital data stream that can be demultiplexed and processed in an appropriate manner by the terminal.

An H.324 multimedia terminal may also be implemented in such a way that it can be connected directly to a digital fixed line network, such as an ISDN (Integrated Services Digital Network). In this case the modem **71** is replaced with an ISDN user-network interface. In FIG. 6, this ISDN user-network interface is represented by alternative block **72**.

H.324 multimedia terminals may also be adapted for use in mobile communication applications. If used with a wireless communication link, the modem **71** can be replaced with any appropriate wireless interface, as represented by alternative block **73** in FIG. 6. For example, an H.324/M multimedia terminal can include a radio transceiver enabling connection to the current 2nd generation GSM mobile telephone network, or the proposed 3rd generation UMTS (Universal Mobile Telephone System).

It should be noted that in multimedia terminals designed for two-way communication, that is for transmission and reception of video data, it is advantageous to provide both a video encoder and video decoder implemented according to the present invention. Such an encoder and decoder pair is often implemented as a single combined functional unit, referred to as a 'codec'.

Because a video encoder according to the invention performs motion compensated video encoding to sub-pixel resolution using a specific interpolation scheme and a particular combination of before-hand and on-demand sub-pixel value interpolation, it is generally necessary for a video

decoder of a receiving terminal to be implemented in a manner compatible with the encoder of the transmitting terminal which formed the compressed video data stream. Failure to ensure this compatibility may have an adverse effect on the quality of the motion compensation and the accuracy of reconstructed video frames.

A typical H.324 multimedia terminal will now be described in further detail with reference to FIG. 6.

The multimedia terminal **60** includes a variety of elements referred to as 'terminal equipment'. This includes video, audio and telematic devices, denoted generically by reference numbers **61**, **62** and **63**, respectively. The video equipment **61** may include, for example, a video camera for capturing video images, a monitor for displaying received video content and optional video processing equipment. The audio equipment **62** typically includes a microphone, for example for capturing spoken messages, and a loudspeaker for reproducing received audio content. The audio equipment may also include additional audio processing units. The telematic equipment **63**, may include a data terminal, keyboard, electronic whiteboard or a still image transceiver, such as a fax unit.

The video equipment **61** is coupled to a video codec **65**. The video codec **65** comprises a video encoder and a corresponding video decoder both implemented according to the invention. Such an encoder and a decoder will be described in the following. The video codec **65** is responsible for encoding captured video data in an appropriate form for further transmission over a communications link and decoding compressed video content received from the communications network. In the example illustrated in FIG. 6, the video codec is implemented according to ITU-T recommendation H.263, with appropriate modifications to implement the sub-pixel value interpolation method according to the invention in both the encoder and the decoder of the video codec.

Similarly, the terminal's audio equipment is coupled to an audio codec, denoted in FIG. 6 by reference number **66**. Like the video codec, the audio codec comprises an encoder/decoder pair. It converts audio data captured by the terminal's audio equipment into a form suitable for transmission over the communications link and transforms encoded audio data received from the network back into a form suitable for reproduction, for example on the terminal's loudspeaker. The output of the audio codec is passed to a delay block **67**. This compensates for the delays introduced by the video coding process and thus ensures synchronisation of audio and video content.

The system control block **64** of the multimedia terminal controls end-to-network signalling using an appropriate control protocol (signalling block **68**) to establish a common mode of operation between a transmitting and a receiving terminal. The signalling block **68** exchanges information about the encoding and decoding capabilities of the transmitting and receiving terminals and can be used to enable the various coding modes of the video encoder. The system control block **64** also controls the use of data encryption. Information regarding the type of encryption to be used in data transmission is passed from encryption block **69** to the multiplexer/de-multiplexer (MUX/DMUX unit) **70**.

During data transmission from the multimedia terminal, the MUX/DMUX unit **70** combines encoded and synchronised video and audio streams with data input from the telematic equipment **63** and possible control data, to form a single bit-stream. Information concerning the type of data encryption (if any) to be applied to the bit-stream, provided by encryption block **69**, is used to select an encryption mode.

Correspondingly, when a multiplexed and possibly encrypted multimedia bit-stream is being received, MUX/DMUX unit **70** is responsible for decrypting the bit-stream, dividing it into its constituent multimedia components and passing those components to the appropriate codec(s) and/or terminal equipment for decoding and reproduction.

It should be noted that the functional elements of the multimedia terminal, video encoder, decoder and video codec according to the invention can be implemented as software or dedicated hardware, or a combination of the two. The video encoding and decoding methods according to the invention are particularly suited for implementation in the form of a computer program comprising machine-readable instructions for performing the functional steps of the invention. As such, the encoder and decoder according to the invention may be implemented as software code stored on a storage medium and executed in a computer, such as a personal desktop computer, in order to provide that computer with video encoding and/or decoding functionality.

If the multimedia terminal **60** is a mobile terminal, that is if it is equipped with a radio transceiver **73**, it will be understood by those skilled in the art that it may also comprise additional elements. In one embodiment it comprises a user interface having a display and a keyboard, which enables operation of the multimedia terminal **60** by a user, together with necessary functional blocks including a central processing unit, such as a microprocessor, which controls the blocks responsible for different functions of the multimedia terminal, a random access memory RAM, a read only memory ROM, and a digital camera. The microprocessor's operating instructions, that is program code corresponding to the basic functions of the multimedia terminal **60**, is stored in the read-only memory ROM and can be executed as required by the microprocessor, for example under control of the user. In accordance with the program code, the microprocessor uses the radio transceiver **73** to form a connection with a mobile communication network, enabling the multimedia terminal **60** to transmit information to and receive information from the mobile communication network over a radio path.

The microprocessor monitors the state of the user interface and controls the digital camera. In response to a user command, the microprocessor instructs the camera to record digital images into the RAM. Once an image is captured, or alternatively during the capturing process, the microprocessor segments the image into image segments (for example macroblocks) and uses the encoder to perform motion compensated encoding for the segments in order to generate a compressed image sequence as explained in the foregoing description. A user may command the multimedia terminal **60** to display the captured images on its display or to send the compressed image sequence using the radio transceiver **73** to another multimedia terminal, a video telephone connected to a fixed line network (PSTN) or some other telecommunications device. In a preferred embodiment, transmission of image data is started as soon as the first segment is encoded so that the recipient can start a corresponding decoding process with a minimum delay.

FIG. **11** is a schematic diagram of a mobile telecommunications network according to an embodiment of the invention. Multimedia terminals MS are in communication with base stations BTS by means of a radio link. The base stations BTS are further connected, through a so-called Abis interface, to a base station controller BSC, which controls and manages several base stations.

The entity formed by a number of base stations BTS (typically, by a few tens of base stations) and a single base

station controller BSC, controlling the base stations, is called a base station subsystem BSS. Particularly, the base station controller BSC manages radio communication channels and handovers. The base station controller BSC is also connected, through a so-called A interface, to a mobile services switching centre MSC, which coordinates the formation of connections to and from mobile stations. A further connection is made, through the mobile service switching centre MSC, to outside the mobile communications network. Outside the mobile communications network there may further reside other network(s) connected to the mobile communications network by gateway(s) GTW, for example the Internet or a Public Switched Telephone Network (PSTN). In such an external network, or within the telecommunications network, there may be located video decoding or encoding stations, such as computers PC. In an embodiment of the invention, the mobile telecommunications network comprises a video server VSRVR to provide video data to a MS subscribing to such a service. The video data is compressed using the motion compensated video compression method as described in the foregoing. The video server may function as a gateway to an online video source or it may comprise previously recorded video clips. Typical videotelephony applications may involve, for example, two mobile stations or one mobile station MS and a video telephone connected to the PSTN, a PC connected to the Internet or a H.261 compatible terminal connected either to the Internet or to the PSTN.

FIG. **7** shows a video encoder **700** according to an embodiment the invention. FIG. **8** shows a video decoder **800** according to an embodiment the invention.

The encoder **700** comprises an input **701** for receiving a video signal from a camera or other video source (not shown). It further comprises a DCT transformer **705**, a quantiser **706**, an inverse quantiser **709**, an inverse DCT transformer **710**, combiners **712** and **716**, a before-hand sub-pixel interpolation block **730**, a frame store **740** and an on-demand sub-pixel interpolation block **750**, implemented in combination with motion estimation block **760**. The encoder also comprises a motion field coding block **770** and a motion compensated prediction block **780**. Switches **702** and **714** are operated co-operatively by a control manager **720** to switch the encoder between an INTRA-mode of video encoding and an INTER-mode of video encoding. The encoder **700** also comprises a multiplexer unit (MUX/DMUX) **790** to form a single bit-stream from the various types of information produced by the encoder **700** for further transmission to a remote receiving terminal, or for example for storage on a mass storage medium such as a computer hard drive (not shown).

It should be noted that the presence and implementations of before-hand sub-pixel interpolation block **730** and on-demand sub-pixel value interpolation block **750** in the encoder architecture depend on the way in which the sub-pixel interpolation method according to the invention is applied. In embodiments of the invention in which before-hand sub-pixel value interpolation is not performed, encoder **700** does not comprise before-hand sub-pixel value interpolation block **730**. In other embodiments of the invention, only before-hand sub-pixel interpolation is performed and thus the encoder does not include on-demand sub-pixel value interpolation block **750**. In embodiments in which both before-hand and on-demand sub-pixel value interpolation are performed, both blocks **730** and **750** are present in the encoder **700**.

Operation of the encoder **700** according to the invention will now be described in detail. In the description, it will be

assumed that each frame of uncompressed video, received from the video source at the input **701**, is received and processed on a macroblock-by-macroblock basis, preferably in raster-scan order. It will further be assumed that when the encoding of a new video sequence starts, the first frame of the sequence is encoded in INTRA-mode. Subsequently, the encoder is programmed to code each frame in INTER-format, unless one of the following conditions is met: 1) it is judged that the current frame being coded is so dissimilar from the reference frame used in its prediction that excessive prediction error information is produced; 2) a predefined INTRA frame repetition interval has expired; or 3) feedback is received from a receiving terminal indicating a request for a frame to be coded in INTRA format.

The occurrence of condition 1) is detected by monitoring the output of the combiner **716**. The combiner **716** forms a difference between the current macroblock of the frame being coded and its prediction, produced in the motion compensated prediction block **780**. If a measure of this difference (for example a sum of absolute differences of pixel values) exceeds a predetermined threshold, the combiner **716** informs the control manager **720** via a control line **717** and the control manager **720** operates the switches **702** and **714** so as to switch the encoder **700** into INTRA coding mode. Occurrence of condition 2) is monitored by means of a timer or frame counter implemented in the control manager **720**, in such a way that if the timer expires, or the frame counter reaches a predetermined number of frames, the control manager **720** operates the switches **702** and **714** to switch the encoder into INTRA coding mode. Condition 3) is triggered if the control manager **720** receives a feedback signal from, for example, a receiving terminal, via control line **718** indicating that an INTRA frame refresh is required by the receiving terminal. Such a condition might arise, for example, if a previously transmitted frame were badly corrupted by interference during its transmission, rendering it impossible to decode at the receiver. In this situation, the receiver would issue a request for the next frame to be encoded in INTRA format, thus re-initialising the coding sequence.

It will further be assumed that the encoder and decoder are implemented in such a way as to allow the determination of motion vectors with a spatial resolution of up to quarter-pixel resolution. As will be seen in the following, finer levels of resolution are also possible.

Operation of the encoder **700** in INTRA coding mode will now be described. In INTRA-mode, the control manager **720** operates the switch **702** to accept video input from input line **719**. The video signal input is received macroblock by macroblock from input **701** via the input line **719** and each macroblock of original image pixels is transformed into DCT coefficients by the DCT transformer **705**. The DCT coefficients are then passed to the quantiser **706**, where they are quantised using a quantisation parameter QP. Selection of the quantisation parameter QP is controlled by the control manager **720** via control line **722**. Each DCT transformed and quantised macroblock that makes up the INTRA coded image information **723** of the frame is passed from the quantiser **706** to the MUX/DMUX **790**. The MUX/DMUX **790** combines the INTRA coded image information with possible control information (for example header data, quantisation parameter information, error correction data etc.) to form a single bit-stream of coded image information **725**. Variable length coding (VLC) is used to reduce redundancy of the compressed video bit-stream, as is known to those skilled in the art.

A locally decoded picture is formed in the encoder **700** by passing the data output by the quantiser **706** through inverse quantiser **709** and applying an inverse DCT transform **710** to the inverse-quantised data. The resulting data is then input to the combiner **712**. In INTRA mode, switch **714** is set so that the input to the combiner **712** via the switch **714** is set to zero. In this way, the operation performed by the combiner **712** is equivalent to passing the decoded image data formed by the inverse quantiser **709** and the inverse DCT transform **710** unaltered.

In embodiments of the invention in which before-hand sub-pixel value interpolation is performed, the output from combiner **712** is applied to before-hand sub-pixel interpolation block **730**. The input to the before-hand sub-pixel value interpolation block **730** takes the form of decoded image blocks. In the before-hand sub-pixel value interpolation block **730**, each decoded macroblock is subjected to sub-pixel interpolation in such a way that a predetermined sub-set of sub-pixel resolution sub-pixel values is calculated according to the interpolation method of the invention and is stored together with the decoded pixel values in frame store **740**.

In embodiments in which before-hand sub-pixel interpolation is not performed, before-hand sub-pixel interpolation block is not present in the encoder architecture and the output from combiner **712**, comprising decoded image blocks, is applied directly to frame store **740**.

As subsequent macroblocks of the current frame are received and undergo the previously described coding and decoding steps in blocks **705**, **706**, **709**, **710**, **712**, a decoded version of the INTRA-frame is built up in the frame store **740**. When the last macroblock of the current frame has been INTRA coded and subsequently decoded, the frame store **740** contains a completely decoded frame, available for use as a prediction reference frame in coding a subsequently received video frame in INTER format. In embodiments of the invention in which before-hand sub-pixel value interpolation is performed, the reference frame held in frame store **740** is at least partially interpolated to sub-pixel resolution.

Operation of the encoder **700** in INTER coding mode will now be described. In INTER coding mode, the control manager **720** operates switch **702** to receive its input from line **721**, which comprises the output of the combiner **716**. The combiner **716** forms prediction error information representing the difference between the current macroblock of the frame being coded and its prediction, produced in the motion compensated prediction block **780**. The prediction error information is DCT transformed in block **705** and quantised in block **706** to form a macroblock of DCT transformed and quantised prediction error information. Each macroblock of DCT transformed and quantised prediction error information is passed from the quantiser **706** to the MUX/DMUX unit **790**. The MUX/DMUX unit **790** combines the prediction error information **723** with motion coefficients **724** (described in the following) and control information (for example header data, quantisation parameter information, error correction data etc.) to form a single bit-stream of coded image information, **725**.

Locally decoded prediction error information for the each macroblock of the INTER coded frame is then formed in the encoder **700** by passing the encoded prediction error information **723** output by the quantiser **706** through the inverse quantiser **709** and applying an inverse DCT transform in block **710**. The resulting locally decoded macroblock of prediction error information is then input to combiner **712**. In INTER-mode, switch **714** is set so that the combiner **712** also receives motion predicted macroblocks for the current

INTER frame, produced in the motion compensated prediction block 780. The combiner 712 combines these two pieces of information to produce reconstructed image blocks for the current INTER frame.

As described above when considering INTRA coded frames, in embodiments of the invention in which before-hand sub-pixel value interpolation is performed, the output from combiner 712 is applied to the before-hand sub-pixel interpolation block 730. Thus, the input to the before-hand sub-pixel value interpolation block 730 in INTER coding mode also takes the form of decoded image blocks. In the before-hand sub-pixel value interpolation block 730, each decoded macroblock is subjected to sub-pixel interpolation in such a way that a predetermined sub-set of sub-pixel values is calculated according to the interpolation method of the invention and is stored together with the decoded pixel values in frame store 740. In embodiments in which before-hand sub-pixel interpolation is not performed, before-hand sub-pixel interpolation block is not present in the encoder architecture and the output from combiner 712, comprising decoded image blocks, is applied directly to frame store 740.

As subsequent macroblocks of the video signal are received from the video source and undergo the previously described coding and decoding steps in blocks 705, 706, 709, 710, 712, a decoded version of the INTER frame is built up in the frame store 740. When the last macroblock of the frame has been INTER coded and subsequently decoded, the frame store 740 contains a completely decoded frame, available for use as a prediction reference frame in encoding a subsequently received video frame in INTER format. In embodiments of the invention in which before-hand sub-pixel value interpolation is performed, the reference frame held in frame store 740 is at least partially interpolated to sub-pixel resolution.

Formation of a prediction for a macroblock of the current frame will now be described.

Any frame encoded in INTER format requires a reference frame for motion compensated prediction. This means, inter alia, that when encoding a video sequence, the first frame to be encoded, whether it is the first frame in the sequence, or some other frame, must be encoded in INTRA format. This, in turn, means that when the video encoder 700 is switched into INTER coding mode by control manager 720, a complete reference frame, formed by locally decoding a previously encoded frame, is already available in the frame store 740 of the encoder. In general, the reference frame is formed by locally decoding either an INTRA coded frame or an INTER coded frame.

The first step in forming a prediction for a macroblock of the current frame is performed by motion estimation block 760. The motion estimation block 760 receives the current macroblock of the frame being coded via line 727 and performs a block matching operation in order to identify a region in the reference frame which corresponds substantially with the current macroblock. According to the invention, the block-matching process is performed to sub-pixel resolution in a manner that depends on the implementation of the encoder 700 and the degree of before-hand sub-pixel interpolation performed. However, the basic principle behind the block-matching process is similar in all cases. Specifically, motion estimation block 760 performs block-matching by calculating difference values (e.g. sums of absolute differences) representing the difference in pixel values between the macroblock of the current frame under examination and candidate best-matching regions of pixels/ sub-pixels in the reference frame. A difference value is produced for all possible offsets (e.g. quarter- or one eighth

sub-pixel precision x, y displacements) between the macroblock of the current frame and candidate test region within a predefined search region of the reference frame and motion estimation block 760 determines the smallest calculated difference value. The offset between the macroblock in the current frame and the candidate test region of pixel values/ sub-pixel values in the reference frame that yields the smallest difference value defines the motion vector for the macroblock in question. In certain embodiments of the invention, an initial estimate for the motion vector having unit pixel precision is first determined and then refined to a finer level of sub-pixel precision, as described in the foregoing.

In embodiments of the encoder in which before-hand sub-pixel value interpolation is not performed, all sub-pixel values required in the block matching process are calculated in on-demand sub-pixel value interpolation block 750. Motion estimation block 760 controls on-demand sub-pixel value interpolation block 750 to calculate each sub-pixel value needed in the block-matching process in an on-demand fashion, as and when it is required. In this case, motion estimation block 760 may be implemented so as to perform block-matching as a one-step process, in which case a motion vector with the desired sub-pixel resolution is sought directly, or it may be implemented so as to perform block-matching as a two step process. If the two-step process is adopted, the first step may comprise a search for e.g. a full or half-pixel resolution motion vector and the second step is performed in order to refine the motion vector to the desired sub-pixel resolution. As block matching is an exhaustive process, in which blocks of nxm pixels in the current frame are compared one-by-one with blocks of nxm pixels or sub-pixels in the interpolated reference frame, it should be appreciated that a sub-pixel calculated in an on-demand fashion by the on-demand pixel interpolation block 750 may need to be calculated multiple times as successive difference values are determined. In a video encoder, this approach is not the most efficient possible in terms of computational complexity/burden.

In embodiments of the encoder which use only before-hand sub-pixel value interpolation, block-matching may be performed as a one step process, as all sub-pixel values of the reference frame required to determine a motion vector with the desired sub-pixel resolution are calculated before-hand in block 730 and stored in frame store 740. Thus, they are directly available for use in the block-matching process and can be retrieved as required from frame store 740 by motion estimation block 760. However, even in the case where all sub-pixel values are available from frame store 740, it is still more computationally efficient to perform block-matching as a two-step process, as fewer difference calculations are required. It should be appreciated that while full before-hand sub-pixel value interpolation reduces computational complexity in the encoder, it is not the most efficient approach in terms of memory consumption.

In embodiments of the encoder in which both before-hand and on-demand sub-pixel value interpolation are used, motion estimation block 760 is implemented in such a way that it can retrieve sub-pixel values previously calculated in before-hand sub-pixel value interpolation block 730 and stored in frame store 740 and further control on-demand sub-pixel value interpolation block 750 to calculate any additional sub-pixel values that may be required. The block-matching process may be performed as a one-step or a two-step process. If a two-step implementation is used, before-hand calculated sub-pixel values retrieved from frame store 740 may be used in the first step of the process

and the second step may be implemented so as to use sub-pixel values calculated by on-demand sub-pixel value interpolation block 750. In this case, certain sub-pixel values used in the second step of the block matching process may need to be calculated multiple times as successive comparisons are made, but the number of such duplicate calculations is significantly less than if before-hand sub-pixel value calculation is not used. Furthermore, memory consumption is reduced with respect to embodiments in which only before-hand sub-pixel value interpolation is used.

Once the motion estimation block 760 has produced a motion vector for the macroblock of the current frame under examination, it outputs the motion vector to the motion field coding block 770. Motion field coding block 770 then approximates the motion vector received from motion estimation block 760 using a motion model. The motion model generally comprises a set of basis functions. More specifically, the motion field coding block 770 represents the motion vector as a set of coefficient values (known as motion coefficients) which, when multiplied by the basis functions, form an approximation of the motion vector. The motion coefficients 724 are passed from motion field coding block 770 to motion compensated prediction block 780. Motion compensated prediction block 780 also receives the pixel/sub-pixel values of the best-matching candidate test region of the reference frame identified by motion estimation block 760. In FIG. 7, these values are shown to be passed via line 729 from on-demand sub-pixel interpolation block 750. In alternative embodiments of the invention, the pixel values in question are provided from the motion estimation block 760 itself.

Using the approximate representation of the motion vector generated by motion field coding block 770 and the pixel/sub-pixel values of the best-matching candidate test region, motion compensated prediction block 780 produces a macroblock of predicted pixel values. The macroblock of predicted pixel values represents a prediction for the pixel values of the current macroblock generated from the interpolated reference frame. The macroblock of predicted pixel values is passed to the combiner 716 where it is subtracted from the new current frame in order to produce prediction error information 723 for the macroblock, as described in the foregoing.

The motion coefficients 724 formed by motion field coding block are also passed to the MUX/DMUX unit 790, where they are combined with prediction error information 723 for the macroblock in question and possible control information from control manager 720 to form an encoded video stream 725 for transmission to a receiving terminal.

Operation of a video decoder 800 according to the invention will now be described. Referring to FIG. 8, the decoder 800 comprises a demultiplexing unit (MUX/DMUX) 810, which receives the encoded video stream 725 from the encoder 700 and demultiplexes it, an inverse quantiser 820, an inverse DCT transformer 830, a motion compensated prediction block 840, a frame store 850, a combiner 860, a control manager 870, an output 880, before-hand sub-pixel value interpolation block 845 and on-demand sub-pixel interpolation block 890 associated with the motion compensated prediction block 840. In practice the control manager 870 of the decoder 800 and the control manager 720 of the encoder 700 may be the same processor. This may be the case if the encoder 700 and decoder 800 are part of the same video codec.

FIG. 8 shows an embodiment in which a combination of before-hand and on-demand sub-pixel value interpolation is used in the decoder. In other embodiments, only before-hand

sub-pixel value interpolation is used, in which case decoder 800 does not include on-demand sub-pixel value interpolation block 890. In a preferred embodiment of the invention, no before-hand sub-pixel value interpolation is used in the decoder and therefore before-hand sub-pixel value interpolation block 845 is omitted from the decoder architecture. If both before-hand and on-demand sub-pixel value interpolation are performed, the decoder comprises both blocks 845 and 890.

The control manager 870 controls the operation of the decoder 800 in response to whether an INTRA or an INTER frame is being decoded. An INTRA/INTER trigger control signal, which causes the decoder to switch between decoding modes is derived, for example, from picture type information provided in the header portion of each compressed video frame received from the encoder. The INTRA/INTER trigger control signal is passed to control manager 870 via control line 815, together with other video codec control signals demultiplexed from the encoded video stream 725 by the MUX/DMUX unit 810.

When an INTRA frame is decoded, the encoded video stream 725 is demultiplexed into INTRA coded macroblocks and control information. No motion vectors are included in the encoded video stream 725 for an INTRA coded frame. The decoding process is performed macroblock-by-macroblock. When the encoded information 723 for a macroblock is extracted from video stream 725 by MUX/DMUX unit 810, it is passed to inverse quantiser 820. The control manager controls inverse quantiser 820 to apply a suitable level of inverse quantisation to the macroblock of encoded information, according to control information provided in video stream 725. The inverse quantised macroblock is then inversely transformed in the inverse DCT transformer 830 to form a decoded block of image information. Control manager 870 controls combiner 860 to prevent any reference information being used in the decoding of the INTRA coded macroblock. The decoded block of image information is passed to the video output 880 of the decoder.

In embodiments of the decoder which employ before-hand sub-pixel value interpolation, the decoded block of image information (i.e. pixel values) produced as a result of the inverse quantisation and inverse transform operations performed in blocks 820 and 830 is passed to before-hand sub-pixel value interpolation block 845. Here, sub-pixel value interpolation is performed according to the method of the invention, the degree of before-hand sub-pixel value interpolation applied being determined by the details of the decoder implementation. In embodiments of the invention in which on-demand sub-pixel value interpolation is not performed, before-hand sub-pixel value interpolation block 845 interpolates all sub-pixel values. In embodiments that use a combination of before-hand and on-demand sub-pixel value interpolation, before-hand sub-pixel value interpolation block 845 interpolates a certain sub-set of sub-pixel values. This may comprise, for example, all sub-pixels at half-pixel locations, or a combination of sub-pixels at half-pixel and one quarter-pixel locations. In any case, after before-hand sub-pixel value interpolation, the interpolated sub-pixel values are stored in frame store 850, together with the original decoded pixel values. As subsequent macroblocks are decoded, before-hand interpolated and stored, a decoded frame, at least partially interpolated to sub-pixel resolution is progressively assembled in the frame store 850 and becomes available for use as a reference frame for motion compensated prediction.

In embodiments of the decoder which do not employ before-hand sub-pixel value interpolation, the decoded

block of image information (i.e. pixel values) produced as a result of the inverse quantisation and inverse transform operations performed on the macroblock in blocks **820** and **830** is passed directly to frame store **850**. As subsequent macroblocks are decoded and stored, a decoded frame, having unit pixel resolution is progressively assembled in the frame store **850** and becomes available for use as a reference frame for motion compensated prediction.

When an INTER frame is decoded, the encoded video stream **725** is demultiplexed into encoded prediction error information **723** for each macroblock of the frame, associated motion coefficients **724** and control information. Again, the decoding process is performed macroblock-by-macroblock. When the encoded prediction error information **723** for a macroblock is extracted from the video stream **725** by MUX/DMUX unit **810**, it is passed to inverse quantiser **820**. Control manager **870** controls inverse quantiser **820** to apply a suitable level of inverse quantisation to the macroblock of encoded prediction error information, according to control information received in video stream **725**. The inverse quantised macroblock of prediction error information is then inversely transformed in the inverse DCT transformer **830** to yield decoded prediction error information for the macroblock.

The motion coefficients **724** associated with the macroblock in question are extracted from the video stream **725** by MUX/DMUX unit **810** and passed to motion compensated prediction block **840**, which reconstructs a motion vector for the macroblock using the same motion model as that used to encode the INTER-coded macroblock in encoder **700**. The reconstructed motion vector approximates the motion vector originally determined by motion estimation block **760** of the encoder. The motion compensated prediction block **840** of the decoder uses the reconstructed motion vector to identify the location of a block of pixel/sub-pixel values in a prediction reference frame stored in frame store **850**. The reference frame may be, for example, a previously decoded INTRA frame, or a previously decoded INTER frame. In either case, the block of pixel/sub-pixel values indicated by the reconstructed motion vector, represents the prediction of the macroblock in question.

The reconstructed motion vector may point to any pixel or sub-pixel. If the motion vector indicates that the prediction for the current macroblock is formed from pixel values (i.e. the values of pixels at unit pixel locations), these can simply be retrieved from frame store **850**, as the values in question are obtained directly during the decoding of each frame. If the motion vector indicates that the prediction for the current macroblock is formed from sub-pixel values, these must either be retrieved from frame store **850**, or calculated in on-demand sub-pixel interpolation block **890**. Whether sub-pixel values must be calculated, or can simply be retrieved from the frame store, depends on the degree of before-hand sub-pixel value interpolation used in the decoder.

In embodiments of the decoder that do not employ before-hand sub-pixel value interpolation, the required sub-pixel values are all calculated in on-demand sub-pixel value interpolation block **890**. On the other hand, in embodiments in which all sub-pixel values are interpolated before-hand, motion compensated prediction block **840** can retrieve the required sub-pixel values directly from the frame store **850**. In embodiments that use a combination before-hand and on-demand sub-pixel value interpolation, the action required in order to obtain the required sub-pixel values depends on which sub-pixel values are interpolated before-hand. Taking as an example an embodiment in which all sub-pixel values at half-pixel locations are calculated before-hand, it is evi-

dent that if a reconstructed motion vector for a macroblock points to a pixel at unit location or a sub-pixel at half-pixel location, all the pixel or sub-pixel values required to form the prediction for the macroblock are present in the frame store **850** and can be retrieved from there by motion compensated prediction block **840**. If, however, the motion vector indicates a sub-pixel at a quarter-pixel location, the sub-pixels required to form the prediction for the macroblock are not present in frame store **850** and are therefore calculated in on-demand sub-pixel value interpolation block **890**. In this case, on-demand sub-pixel value interpolation block **890** retrieves any pixel or sub-pixel required to perform the interpolation from frame store **850** and applies the interpolation method described below. Sub-pixel values calculated in on-demand sub-pixel value interpolation block **890** are passed to motion compensated prediction block **840**.

Once a prediction for a macroblock has been obtained, the prediction (that is, a macroblock of predicted pixel values) is passed from motion compensated prediction block **840** to combiner **860** where it combined with the decoded prediction error information for the macroblock to form a reconstructed image block which, in turn, is passed to the video output **880** of the decoder.

It should be appreciated that in practical implementations of encoder **700** and decoder **800**, the extent to which frames are before-hand sub-pixel interpolated, and thus the amount of on-demand sub-pixel value interpolation that is performed, can be chosen according to, or dictated by, the hardware implementation of the video encoder **700**, or the environment in which it is intended to be used. For example, if the memory available to the video encoder is limited, or memory must be reserved for other functions, it is appropriate to limit the amount of before-hand sub-pixel value interpolation that is performed. In other cases, where the microprocessor performing the video encoding operation has limited processing capacity, e.g. the number of operations per second that can be executed is comparatively low, it is more appropriate to restrict the amount of on-demand sub-pixel value interpolation that is performed. In a mobile communications environment, for example, when video encoding and decoding functionality is incorporated in a mobile telephone or similar wireless terminal for communication with a mobile telephone network, both memory and processing power may be limited. In this case a combination of before-hand and on-demand sub-pixel value interpolation may be the best choice to obtain an efficient implementation in the video encoder. In video decoder **800**, use of before-hand sub-pixel value is generally not preferred, as it typically results in the calculation of many sub-pixel values that are not actually used in the decoding process. However, it should be appreciated that although different amounts of before-hand and on-demand interpolation can be used in the encoder and decoder in order to optimise the operation of each, both encoder and decoder can be implemented so as to use the same division between before-hand and on-demand sub-pixel value interpolation.

Although the foregoing description does not describe the construction of bi-directionally predicted frames (B-frames) in the encoder **700** and the decoder **800**, it should be understood that in embodiments of the invention, such a capability may be provided. Provision of such capability is considered within the ability of one skilled in the art.

An encoder **700** or a decoder **800** according to the invention can be realised using hardware or software, or using a suitable combination of both. An encoder or decoder implemented in software may be, for example, a separate program or a software building block that can be used by

35

various programs. In the above description and in the drawings, the functional blocks are represented as separate units, but the functionality of these blocks can be implemented, for example, in one software program unit.

The encoder **700** and decoder **800** can further be combined in order to form a video codec having both encoding and decoding functionality. In addition to being implemented in a multimedia terminal, such a codec may also be implemented in a network. A codec according to the invention may be a computer program or a computer program element, or it may be implemented at least partly using hardware.

The sub-pixel interpolation method used in the encoder **700** and decoder **800** according to the invention now be described in detail. The method will first be introduced at a general conceptual level and then two preferred embodiments will be described. In the first preferred embodiment, sub-pixel value interpolation is performed to $\frac{1}{4}$ pixel resolution and in the second the method is extended to $\frac{1}{8}$ pixel resolution.

It should be noted that interpolation must produce identical values in the encoder and the decoder, but its implementation should be optimized for both entities separately. For example, in an encoder according to the first embodiment of the invention in which sub-pixel value interpolation is performed to $\frac{1}{4}$ pixel resolution, it is most efficient to calculate $\frac{1}{2}$ resolution pixels before-hand and to calculate values for $\frac{1}{4}$ resolution sub-pixels in an on-demand fashion, only when they are needed during motion estimation. This has the effect of limiting memory usage while keeping the computational complexity/burden at an acceptable level. In the decoder, on the other hand, it is advantageous not to pre-calculate any of the sub-pixels. Therefore, it should be appreciated that a preferred embodiment of the decoder does not include before-hand sub-pixel value interpolation block **845** and all sub-pixel value interpolation is performed in on-demand sub-pixel value interpolation block **890**.

In the description of the interpolation method provided below, references are made to the pixel positions depicted in FIG. **14a**. In this figure pixels labelled A represent original pixels (that is, pixels residing at unit horizontal and vertical locations). Pixels labelled with other letters represent sub-pixels that are to be interpolated. The description that follows will adhere to the previously introduced conventions regarding the description of pixel and sub-pixel locations.

Next, the steps required to interpolate all sub-pixel positions are described:

Values for the $\frac{1}{2}$ resolution sub-pixels labelled b are obtained by first calculating an intermediate value b using a Kth order filter, according to:

$$b = \sum_{i=1}^K x_i A_i \quad (9)$$

where x_i is a vector of filter coefficients, A_i is a corresponding vector of original pixel values A situated at unit horizontal and unit vertical locations, and K is an integer which defines the order of the filter. Thus, equation 9 can be re-expressed as:

$$b = x_1 A_1 + x_2 A_2 + x_3 A_3 + \dots + x_{K-1} A_{K-1} + x_K A_K \quad (10)$$

The values of the filter coefficients x_i and the order of the filter K may vary from embodiment to embodiment. Equally, different coefficient values may be used in the calculation of

36

different sub-pixels within an embodiment. In other embodiments, the values of filter coefficients x_i and the order of the filter may depend on which of the $\frac{1}{2}$ resolution b sub-pixels is being interpolated. Pixels A_i are disposed symmetrically with respect to the $\frac{1}{2}$ resolution sub-pixel b being interpolated and are the closest neighbours of that sub-pixel. In the case of the $\frac{1}{2}$ resolution sub-pixel b situated at half horizontal and unit vertical location, pixels A_i are disposed horizontally with respect to b (as shown in FIG. **14b**). If the $\frac{1}{2}$ resolution sub-pixel b situated at unit horizontal and half vertical location is being interpolated, pixels A_i are disposed vertically with respect to b (as shown in FIG. **14c**).

A final value for $\frac{1}{2}$ resolution sub-pixel b is calculated by dividing intermediate value b by a constant scale₁, truncating it to obtain an integer number and clipping the result to lie in the range [0, 2ⁿ-1]. In alternative embodiments of the invention rounding may be performed instead of truncation. Preferably, constant scale₁ is chosen to be equal to the sum of filter coefficients x_i .

A value for the $\frac{1}{2}$ resolution sub-pixel labelled c is also obtained by first calculating an intermediate value c using an Mth order filter, according to:

$$c = \sum_{i=1}^M y_i b_i \quad (11)$$

where y_i is a vector of filter coefficients, b_i is a corresponding vector of intermediate values b_i in the horizontal or vertical direction. i.e.:

$$c = y_1 b_1 + y_2 b_2 + y_3 b_3 + \dots + y_{M-1} b_{M-1} + y_M b_M \quad (12)$$

The values of the filter coefficients y_i and the order of the filter M may vary from embodiment to embodiment. Equally, different coefficient values may be used in the calculation of different sub-pixels within an embodiment. Preferably, the b values are intermediate values for $\frac{1}{2}$ resolution sub-pixels b which are disposed symmetrically with respect to $\frac{1}{2}$ resolution sub-pixel c and are the closest neighbours of sub-pixel c. In an embodiment of the invention, the $\frac{1}{2}$ resolution sub-pixels b are disposed horizontally with respect to sub-pixel c, in an alternative embodiment they are disposed vertically with respect to sub-pixel c.

A final value of $\frac{1}{2}$ resolution sub-pixel c is computed by dividing intermediate value c by a constant scale₂, truncating it to obtain an integer number and clipping the result to lie in the range [0, 2ⁿ-1]. In alternative embodiments of the invention rounding may be performed instead of truncation. Preferably, constant scale₂ is equal to scale₁*scale₁.

It should be noted that the use of intermediate values b in the horizontal direction leads to the same result as using intermediate values b in the vertical direction.

There are two alternatives for interpolating values for the $\frac{1}{4}$ resolution sub-pixels labelled h. Both involve linear interpolation along a diagonal line linking $\frac{1}{2}$ resolution sub-pixels neighbouring the $\frac{1}{4}$ resolution sub-pixel h being interpolated. In a first embodiment, a value for sub-pixel h is calculated by averaging the values of the two $\frac{1}{2}$ resolution sub-pixels b closest to sub-pixel h. In a second embodiment, a value for sub-pixel h is calculated by averaging the values of the closest pixel A and the closest $\frac{1}{2}$ resolution sub-pixel c. It should be appreciated that this provides the possibility of using different combinations of diagonal interpolations to determine the values for sub-pixels h within the confines of different groups of 4 image pixels A. However, it should also

be realised that the same combination should be used in both the encoder and the decoder in order to produce identical interpolation results. FIG. 15 depicts 4 possible choices of diagonal interpolation for sub-pixels h in adjacent groups of 4 pixels within an image. Simulations in the TML environment have verified that both embodiments result in similar compression efficiency. The second embodiment has higher complexity, since calculation of sub-pixel c requires calculation of several intermediate values. Therefore the first embodiment is preferred.

Values for $\frac{1}{4}$ resolution sub-pixels labelled d and g are calculated from the values of their nearest horizontal neighbours using linear interpolation. In other words, a value for $\frac{1}{4}$ resolution sub-pixel d is obtained by averaging values of its nearest horizontal neighbours, original image pixel A and $\frac{1}{2}$ resolution sub-pixel b. Similarly, a value for $\frac{1}{4}$ resolution sub-pixel g is obtained by taking the average of its two nearest horizontal neighbours, $\frac{1}{2}$ resolution sub-pixels b and c.

Values for $\frac{1}{4}$ resolution sub-pixels labelled e, f and i are calculated from the values of their nearest neighbours in the vertical direction using linear interpolation. More specifically, a value for $\frac{1}{4}$ resolution sub-pixel e is obtained by averaging the values of its two nearest vertical neighbours, original image pixel A and $\frac{1}{2}$ resolution sub-pixel b. Similarly, a value for $\frac{1}{4}$ resolution sub-pixel f is obtained by taking the average of its two nearest vertical neighbours, $\frac{1}{2}$ resolution sub-pixels b and c. In an embodiment of the invention, a value for $\frac{1}{4}$ resolution sub-pixel i is obtained in manner identical to that just described in connection with $\frac{1}{4}$ resolution sub-pixel f. However, in an alternative embodiment of the invention, and in common with the H.26 test models TML5 and TML6 previously described, $\frac{1}{4}$ resolution sub-pixel i is determined using the values of the four closest original image pixels, according to $(A_1 + A_2 + A_3 + A_4 + 2)/4$.

It should also be noted that in all cases where an average involving pixel and/or sub-pixel values is determined, the average may be formed in any appropriate manner. For example, the value for $\frac{1}{4}$ resolution sub-pixel d can be defined as $d = (A+b)/2$ or as $d = (A+b+1)/2$. The addition of 1 to the sum of values for pixel A and $\frac{1}{2}$ resolution sub-pixel b has the effect of causing any rounding or truncation operation subsequently applied to round or truncate the value for d to the next highest integer value. This is true for any sum of integer values and may be applied to any of the averaging operations performed according to the method of the invention in order to control rounding or truncation effects.

It should be noted that the sub-pixel value interpolation method according to the invention provides advantages over each of TML5 and TML6.

In contrast to TML5, in which the values of some of the $\frac{1}{4}$ resolution sub-pixels depend on previously interpolated values obtained for other $\frac{1}{4}$ resolution sub-pixels, in the method according to the invention, all $\frac{1}{4}$ resolution sub-pixels are calculated from original image pixels or $\frac{1}{2}$ resolution sub-pixel positions using linear interpolation. Thus, the reduction in precision of those $\frac{1}{4}$ resolution sub-pixel values which occurs in TML5 due to the intermediate truncation and clipping of the other $\frac{1}{4}$ resolution sub-pixels from which they are calculated, does not take place in the method according to the invention. In particular, referring to FIG. 14a, $\frac{1}{4}$ resolution sub-pixels h (and sub-pixel i in one embodiment of the invention) are interpolated diagonally in order to reduce dependency on other $\frac{1}{4}$ -pixels. Furthermore, in the method according to the invention, the

number of calculations (and therefore the number of processor cycles) required to obtain a value for those $\frac{1}{4}$ resolution sub-pixels in the decoder is reduced compared with TML5. Additionally, the calculation of any $\frac{1}{4}$ resolution sub-pixel value requires a number of calculations which is substantially similar to the number of calculations required to determine any other $\frac{1}{4}$ resolution sub-pixel value. More specifically, in a situation where the required $\frac{1}{2}$ resolution sub-pixel values are already available, e.g. they have been calculated before-hand, the number of calculations required to interpolate a $\frac{1}{4}$ resolution sub-pixel value from the pre-calculated $\frac{1}{2}$ resolution sub-pixel values is the same as the number of calculations required to calculate any other $\frac{1}{4}$ resolution sub-pixel value from the available $\frac{1}{2}$ resolution sub-pixel values.

In comparison with TML6, the method according to the invention does not require high precision arithmetic to be used in the calculation of all sub-pixels. Specifically, as all of the $\frac{1}{4}$ resolution sub-pixel values are calculated from original image pixels or $\frac{1}{2}$ resolution sub-pixel values using linear interpolation, lower precision arithmetic can be used in their interpolation. Consequently, in hardware implementations of the inventive method, for example in an ASIC (Application Specific Integrated Circuit), the use of lower precision arithmetic reduces the number of components (e.g. gates) that must be devoted to the calculation of $\frac{1}{4}$ resolution sub-pixel values. This, in turn, reduces the overall area of silicon that must be dedicated to the interpolation function. As the majority of sub-pixels are, in fact, $\frac{1}{4}$ resolution sub-pixels (12 out of the 15 sub-pixels illustrated in FIG. 14a), the advantage provided by the invention in this respect is particularly significant. In software implementations, where sub-pixel interpolation is performed using the standard instruction set of a general purpose CPU (Central Processor Unit) or using a DSP (Digital Signal Processor), a reduction in the precision of the arithmetic required generally leads to an increase in the speed at which the calculations can be performed. This is particularly advantageous in 'low cost' implementations, in which it is desirable to use a general purpose CPU rather than any form of ASIC.

The method according to the invention provides still further advantages compared with TML5. As mentioned previously, in the decoder only 1 out of the 15 sub-pixel positions is required at any given time, namely that which is indicated by received motion vector information. Therefore, it is advantageous if the value of a sub-pixel in any sub-pixel location can be calculated with the minimum number of steps that result in a correctly interpolated value. The method according to the invention provides this capability. As mentioned in the detailed description provided above, $\frac{1}{2}$ resolution sub-pixel c can be interpolated by filtering in either the vertical or the horizontal direction, the same value being obtained for c regardless of whether horizontal or vertical filtering is used. The decoder can therefore take advantage of this property when calculating values for $\frac{1}{4}$ resolution sub-pixels f and g in such a way as to minimise the number of operations required in order to obtain the required values. For example, if the decoder requires a value for $\frac{1}{4}$ resolution sub-pixel f, $\frac{1}{2}$ resolution sub-pixel c should be interpolated in the vertical direction. If a value is required for $\frac{1}{4}$ resolution sub-pixel g, it is advantageous to interpolate a value for c in the horizontal direction. Thus, in general, it can be said that the method according to the invention provides flexibility in the way in which values are derived for certain $\frac{1}{4}$ resolution sub-pixels. No such flexibility is provided in TML5.

Two specific embodiments will now be described in detail. The first represents a preferred embodiment for calculating sub-pixels with up to $\frac{1}{4}$ pixel resolution, while in the second, the method according to the invention is extended to the calculation of values for sub-pixels having up to $\frac{1}{8}$ pixel resolution. For both embodiments a comparison is provided between the computational complexity/ burden resulting from use of the method according to the invention and that which would result from use of the interpolation methods according to TML5 and TML6 in equivalent circumstances.

The preferred embodiment for interpolating sub-pixels at $\frac{1}{4}$ pixel resolution will be described with reference to FIGS. 14a, 14b and 14c. In the following, it will be assumed that all image pixels and final interpolated values for sub-pixels are represented with 8-bits.

Calculation of $\frac{1}{2}$ resolution sub-pixels at i) half unit horizontal and unit vertical locations and ii) unit horizontal and half unit vertical locations.

1. A value for the sub-pixel at half unit horizontal and unit vertical location, that is $\frac{1}{2}$ resolution sub-pixel b in FIG. 14a, is obtained by first calculating intermediate value $b = (A_1 - 5A_2 + 20A_3 + 20A_4 - 5A_5 + A_6)$ using the values of the six pixels (A_1 to A_6) which are situated at unit horizontal and unit vertical locations in either the row or the column of pixels containing b and which are disposed symmetrically about b, as shown in FIGS. 14b and 14c. A final value for $\frac{1}{2}$ resolution sub-pixel b is calculated as $(b+16)/32$ where the operator/denotes division with truncation. The result is clipped to lie in the range $[0, 255]$.

Calculation of $\frac{1}{2}$ resolution sub-pixels at half unit horizontal and half unit vertical locations.

2. A value for the sub-pixel at half unit horizontal and half unit vertical location, that is $\frac{1}{2}$ resolution sub-pixel c in FIG. 14a, is calculated as $c = (b_1 - 5b_2 + 20b_3 + 20b_4 - 5b_5 + b_6 + 512)/1024$ using the intermediate values b for the six closest $\frac{1}{2}$ resolution sub-pixels which are situated in either the row or the column of sub-pixels containing c and which are disposed symmetrically about c. Again, operator/denotes division with truncation and the result is clipped to lie in the range $[0, 255]$. As previously explained, using intermediate values b for $\frac{1}{2}$ resolution sub-pixels b in the horizontal direction leads to the same result as using intermediate values b for $\frac{1}{2}$ resolution sub-pixels b in the vertical direction. Thus, in an encoder according to the invention, the direction for interpolating $\frac{1}{2}$ resolution sub-pixels b can be chosen according to a preferred mode of implementation. In a decoder according to the invention, the direction for interpolating sub-pixels b is chosen according to which, if any, $\frac{1}{4}$ resolution sub-pixels will be interpolated using the result obtained for $\frac{1}{2}$ resolution sub-pixel c.

Calculation of $\frac{1}{4}$ resolution sub-pixels at i) quarter unit horizontal and unit vertical locations; ii) quarter unit horizontal and half unit vertical locations; iii) unit horizontal and quarter unit vertical locations; and iv) half unit horizontal and quarter unit vertical locations.

3. Values for $\frac{1}{4}$ resolution sub-pixels d, situated at quarter unit horizontal and unit vertical locations are calculated according to $d = (A+b)/2$ using the nearest original image pixel A and the closest $\frac{1}{2}$ resolution sub-pixel b in the horizontal direction. Similarly, values for $\frac{1}{4}$ resolution sub-pixels g, situated at quarter unit horizontal and half unit vertical locations are calculated according to $g = (b+c)/2$ using the two nearest $\frac{1}{2}$ reso-

lution sub-pixels in the horizontal direction. In a similar manner, values for $\frac{1}{4}$ resolution sub-pixels e, situated at unit horizontal and quarter unit vertical locations, are calculated according to $e = (A+b)/2$ using the nearest original image pixel A and the closest $\frac{1}{2}$ resolution sub-pixel b in the vertical direction. Values for $\frac{1}{4}$ resolution sub-pixels f, situated at half unit horizontal and quarter unit vertical locations, are determined from $f = (b+c)/2$ using the two nearest $\frac{1}{2}$ resolution sub-pixel in the vertical direction. In all cases, operator/denotes division with truncation.

Calculation of $\frac{1}{4}$ resolution sub-pixels at quarter unit horizontal and quarter unit vertical locations.

4. Values for $\frac{1}{4}$ resolution sub-pixels h, situated at quarter unit horizontal and quarter unit vertical locations are calculated according to $h = (b_1 + b_2)/2$, using the two nearest $\frac{1}{2}$ resolution sub-pixels b in the diagonal direction. Again, operator/denotes division with truncation.
5. A value for the $\frac{1}{4}$ resolution sub-pixel labeled i is computed from $i = (A_1 + A_2 + A_3 + A_4 + 2)/4$ using the four nearest original pixels A. Once more, operator/denotes division with truncation.

An analysis of the computational complexity of the first preferred embodiment of the invention will now be presented.

In the encoder, it is likely that the same sub-pixel values will be calculated multiple times. Therefore, and as previously explained, the complexity of the encoder can be reduced by pre-calculating all sub-pixel values and storing them in memory. However, this solution increases memory usage by a large margin. In the preferred embodiment of the invention, in which motion vector accuracy is $\frac{1}{4}$ pixel resolution in both the horizontal and vertical dimensions, storing pre-calculated sub-pixel values for the whole image requires 16 times the memory required to store the original, non-interpolated image. To reduce memory usage, all $\frac{1}{2}$ resolution sub-pixels can be interpolated before-hand and $\frac{1}{4}$ resolution sub-pixels can be calculated on-demand, that is, only when they are needed. According to the method of the invention, on-demand interpolation of values for $\frac{1}{4}$ resolution sub-pixels only requires linear interpolation from $\frac{1}{2}$ resolution sub-pixels. Four times the original picture memory is required to store the pre-calculated $\frac{1}{2}$ resolution sub-pixels since only 8 bits are necessary to represent them.

However, if the same strategy of pre-calculating all $\frac{1}{2}$ resolution sub-pixels using before-hand interpolation is used in conjunction with the direct interpolation scheme of TML6, the memory requirements increase to 9 times the memory required to store the original non-interpolated image. This results from the fact that a larger number of bits is required to store the high precision intermediate values associated with each $\frac{1}{2}$ resolution sub-pixel in TML6. In addition, the complexity of sub-pixel interpolation during motion estimation is higher in TML6, since scaling and clipping has to be performed for every $\frac{1}{2}$ and $\frac{1}{4}$ sub-pixel location.

In the following, the complexity of the sub-pixel value interpolation method according to the invention, when applied in a video decoder, is compared with that of the interpolation schemes used in TML5 and TML6. Throughout the analysis which follows, it is assumed that in each method the interpolation of any sub-pixel value is performed using only the minimum number of steps required to obtain a correctly interpolated value. It is further assumed that each method is implemented in a block based manner, that is, intermediate values common for all the sub-pixels to be interpolated in a particular $N \times M$ block are calculated only

once. An illustrative example is provided in FIG. 16. Referring to FIG. 16, it can be seen that in order to calculate a 4×4 block of $\frac{1}{2}$ resolution sub-pixels c, a 9×4 block of $\frac{1}{2}$ resolution sub-pixels b is first calculated.

Compared with the sub-pixel value interpolation method used in TML5, the method according to the invention has a lower computational complexity for the following reasons:

1. Unlike the sub-pixel value interpolation scheme used in TML5, according to the method of the invention, a value for $\frac{1}{2}$ resolution sub-pixel c can be obtained by filtering in either the vertical or the horizontal direction. Thus, in order to reduce the number of operations, $\frac{1}{2}$ resolution sub-pixel c can be interpolated in the vertical direction if a value for $\frac{1}{4}$ resolution sub-pixel f is required and in the horizontal direction if a value for $\frac{1}{4}$ resolution sub-pixel g is required. As an example, FIG. 17 shows all the $\frac{1}{2}$ resolution sub-pixel values that must be calculated in order to interpolate values for $\frac{1}{4}$ resolution sub-pixels g in an image block defined by 4×4 original image pixels using the interpolation method of TML5 (FIG. 17a) and using the method according to the invention (FIG. 17b). In this example, the sub-pixel value interpolation method according to TML5 requires a total of $88\frac{1}{2}$ resolution sub-pixels to be interpolated, while the method according to the invention requires the calculation of $72\frac{1}{2}$ resolution sub-pixels. As can be seen from FIG. 17b, according to the invention, $\frac{1}{2}$ resolution sub-pixels c are interpolated in the horizontal direction in order to reduce the number of calculations required.
2. According to the method of the invention, $\frac{1}{4}$ resolution sub-pixel h is calculated by linear interpolation from its two closest neighbouring $\frac{1}{2}$ resolution sub-pixels in the diagonal direction. The respective numbers of $\frac{1}{2}$ resolution sub-pixels that must be calculated in order to obtain values for $\frac{1}{4}$ resolution sub-pixels h within a 4×4 block of original image pixels using the sub-pixel value interpolation method according to TML5 and the method according to the invention are shown in FIGS. 18(a) and 18(b), respectively. Using the method according to TML5 it is necessary to interpolate a total of $56\frac{1}{2}$ resolution sub-pixels, while according to the method of the invention it is necessary to interpolate $40\frac{1}{2}$ resolution sub-pixels.

Table 1 summarizes the decoder complexities of the three sub-pixel value interpolation methods considered here, that according to TML5, the direct interpolation method used in TML6 and the method according to the invention. Complexity is measured in terms of the number of 6-tap filtering and linear interpolation operations performed. It is assumed that Interpolation of $\frac{1}{4}$ resolution sub-pixel i is calculated according to $i = (A_1 + A_2 + A_3 + A_4 + 2)/4$ which is bilinear interpolation and effectively comprises two linear interpolation operations. The operations needed to interpolate sub-pixel values with one 4×4 block of original image pixels are listed for each of the 15 sub-pixel positions which, for convenience of reference, are numbered according to the scheme shown in FIG. 19. Referring to FIG. 19, location 1 is the location of an original image pixel A and locations 2 to 16 are sub-pixel locations. Location 16 is the location of $\frac{1}{4}$ resolution sub-pixel i. In order to compute the average number of operations it has been assumed that the probability of a motion vector pointing to each sub-pixel position is the same. The average complexity is therefore the average of the 15 sums calculated for each sub-pixel location and the single full-pixel location.

TABLE 1

Complexity of $\frac{1}{4}$ resolution sub-pixel interpolation in TML5, TML6 and the method according to the invention.

Location	TML5		TML6		Inventive Method	
	linear.	6-tap	linear.	6-tap	linear.	6-tap
1	0	0	0	0	0	0
3, 9	0	16	0	16	0	16
2, 4, 5, 13	16	16	0	16	16	16
11	0	52	0	52	0	52
7, 15	16	52	0	52	16	52
10, 12	16	68	0	52	16	52
6, 8, 14	48	68	0	52	16	32
16	32	0	32	0	32	0
Average	19	37	2	32	13	28.25

It can be seen from Table 1 that the method according to the invention requires fewer 6-tap filter operations than the sub-pixel value interpolation method according to TML6 and only a few additional linear interpolation operations. Since 6-tap filter operations are much more complex than linear interpolation operations the complexity of the two methods is similar. The sub-pixel value interpolation method according to TML5 has a considerably higher complexity.

The preferred embodiment for interpolating sub-pixels with up to $\frac{1}{8}$ pixel resolution will now be described with reference to FIGS. 20, 21 and 22.

FIG. 20 presents the nomenclature used to describe pixels, $\frac{1}{2}$ resolution sub-pixels, $\frac{1}{4}$ resolution sub-pixels and $\frac{1}{8}$ resolution sub-pixels in this extended application of the method according to the invention.

1. Values for the $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixels labelled b^1 , b^2 and b^3 in FIG. 20 are obtained by first calculating intermediate values $b^1 = (-3A_1 + 12A_2 - 37A_3 + 229A_4 + 71A_5 - 21A_6 + 6A_7 - A_8)$; $b^2 = (-3A_1 + 12A_2 - 39A_3 + 158A_4 + 158A_5 - 39A_6 + 12A_7 - 3A_8)$; and $b^3 = (-A_1 + 6A_2 - 21A_3 + 71A_4 + 229A_5 - 37A_6 + 13A_7 - 3A_8)$ using the values of the eight nearest image pixels (A_1 to A_8) situated at unit horizontal and unit vertical locations in either the row or the column containing b^1 , b^2 and b^3 and disposed symmetrically about $\frac{1}{2}$ resolution sub-pixel b^2 . The asymmetries in the filter coefficients used to obtain intermediate values b^1 and b^3 account for the fact that pixels A_1 to A_8 are not symmetrically located with respect to $\frac{1}{4}$ resolution sub-pixels b^1 and b^3 . Final values for sub-pixels b^i , $i=1, 2, 3$ are calculated according to $b^i = (b^i + 128)/256$ where the operator/ denotes division with truncation. The result is clipped to lie in the range $[0, 255]$.

2. Values for the $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixels labelled c^{1j} , $i, j=1, 2, 3$, are calculated according to $c^{1j} = (-3b_1^j + 12b_2^j - 37b_3^j + 229b_4^j + 71b_5^j - 21b_6^j + 6b_7^j - b_8^j + 32768)/65536$, $c^{2j} = (-3b_1^j + 12b_2^j - 39b_3^j + 158b_4^j + 158b_5^j - 39b_6^j + 12b_7^j - 3b_8^j + 32768)/65536$ and $c^{3j} = (-b_1^j + 6b_2^j - 21b_3^j + 71b_4^j + 229b_5^j - 37b_6^j + 13b_7^j - 3b_8^j + 32768)/65536$ using the intermediate values b^1 , b^2 and b^3 calculated for the eight closest sub-pixels (b_1^j to b_8^j) in the vertical direction, sub-pixels b^j being situated in the column comprising the $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixels c^{1j} being interpolated and disposed symmetrically about the $\frac{1}{2}$ resolution sub-pixel c^{2j} . The asymmetries in the filter coefficients used to obtain values for sub-pixels c^{1j} and c^{3j} account for the fact that sub-pixels b_1^j to b_8^j are not symmetrically located with respect to $\frac{1}{4}$ resolution sub-pixels c^{1j} and c^{3j} . Once more, operator/ denotes division with truncation. Before

the interpolated values for sub-pixels $c^{1/2}$ are stored in the frame memory they are clipped to lie in the range [0, 255]. In an alternative embodiment of the invention, $1/2$ resolution and $1/4$ resolution sub-pixels $c^{1/2}$ are calculated using in an analogous manner using intermediate values b^1 , b^2 and b^3 in the horizontal direction.

3. Values for $1/8$ resolution sub-pixels labelled d are calculated using linear interpolation from the values of their closest neighbouring image pixel, $1/2$ resolution or $1/4$ resolution sub-pixels in the horizontal or vertical direction. For example, upper leftmost $1/8$ resolution sub-pixel d is calculated according to $d=(A+b^1+1)/2$. As before, operator/indicates division with truncation.
4. Values for $1/8$ resolution sub-pixels labelled e and f are calculated using linear interpolation from the values of image pixels, $1/2$ resolution or $1/4$ resolution sub-pixels in the diagonal direction. For example, referring to FIG. 20, upper leftmost pixel $1/8$ resolution sub-pixel e is calculated according to $e=(b^1+b^1+1)/2$. The diagonal direction to be used in the interpolation of each $1/8$ resolution sub-pixel in a first preferred embodiment of the invention, hereinafter referred to as 'preferred method 1', is indicated in FIG. 21(a). Values for $1/8$ resolution sub-pixels labelled g are calculated according to $g=(A+3c^{22}+3)/4$. As always, operator/denotes division with truncation. In an alternative embodiment of the invention, hereinafter referred to as 'preferred method 2', computational complexity is further reduced by interpolating $1/8$ resolution sub-pixels f using linear interpolation from $1/2$ resolution sub-pixels b^2 , that is, according to the relationship $f=(3b^2+b^2+2)/4$. The b^2 sub-pixel which is closer to f is multiplied by 3. The diagonal interpolation scheme used in this alternative embodiment of the invention is depicted in FIG. 21(b). In further alternative embodiments, different diagonal interpolation schemes can be envisaged.

It should be noted that in all cases where an average involving pixel and/or sub-pixel values is used in the determination of $1/8$ resolution sub-pixels, the average may be formed in any appropriate manner. The addition of 1 to the sum of values used in calculating such an average has the effect of causing any rounding or truncation operation subsequently applied to round or truncate the average in question to the next highest integer value. In alternative embodiments of the invention, the addition of 1 is not used.

As in the case of sub-pixel value interpolation to $1/4$ pixel resolution previously described, memory requirements in

the encoder can be reduced by pre-calculating only a part of the sub-pixel values to be interpolated. In the case of sub-pixel value interpolation to $1/8$ pixel resolution, it is advantageous to calculate all $1/2$ resolution and $1/4$ resolution sub-pixels before-hand and to compute values for $1/8$ resolution sub-pixels in an on-demand fashion, only when they are required. When this approach is taken, both the interpolation method according to TML5 and that according to the invention require 16 times the original picture memory to store the $1/2$ resolution and $1/4$ resolution sub-pixel values. However, if the direct interpolation method according to TML6 is used in the same way, intermediate values for the $1/2$ resolution and $1/4$ pixel resolution sub-pixels must be stored. These intermediate values are represented with 32-bit precision and this results in a memory requirement 64 times that for the original, non-interpolated image.

In the following, the complexity of the sub-pixel value interpolation method according to the invention, when applied in a video decoder to calculate values for sub-pixels at up to $1/8$ pixel resolution, is compared with that of the interpolation schemes used in TML5 and TML6. As in the equivalent analysis for $1/4$ pixel resolution sub-pixel value interpolation described above, it is assumed that in each method the interpolation of any sub-pixel value is performed using only the minimum number of steps required to obtain a correctly interpolated value. It is also assumed that each method is implemented in a block based manner, such that intermediate values common for all the sub-pixels to be interpolated in a particular $N \times M$ block are calculated only once.

Table 2 summarizes complexities of the three interpolation methods. Complexity is measured in terms of the number of 8-tap filter and linear interpolation operations performed in each method. The table presents the number of operations required to interpolate each of the $63 \times 1/8$ resolution sub-pixels within one 4×4 block of original image pixels, each sub-pixel location being identified with a corresponding number, as illustrated in FIG. 22. In FIG. 22, location 1 is the location of an original image pixel and locations 2 to 64 are sub-pixel locations. When computing the average number of operations, it has been assumed that the probability of a motion vector pointing to each sub-pixel position is the same. The average complexity is thus the average of the 63 sums calculated for each sub-pixel location and the single full-pixel location.

TABLE 2

Complexity of $1/8$ resolution sub-pixel interpolation in TML5, TML6 and the method according to the invention. (Results shown separately for Preferred Method 1 and Preferred Method 2).

Location	TML5		TML6		Preferred Method 1		Preferred Method 2	
	linear.	8-tap	linear.	8-tap	linear.	8-tap	linear.	8-tap
1	0	0	0	0	0	0	0	0
3, 5, 7, 17, 33, 49	0	16	0	16	0	16	0	16
19, 21, 23, 35, 37, 39, 51, 53, 55	0	60	0	60	0	60	0	60
2, 8, 9, 57	16	16	0	16	16	16	16	16

18, 24, 34, 40, 50, 56	16	76	0	60	16	60	16	60
12, 14, 60, 62	32	120	0	60	16	32	16	32
26, 32, 42, 48	32	108	0	60	16	32	16	32
20, 22, 36, 38, 52, 54	16	120	0	60	16	76	16	76
27, 29, 31, 43, 45, 47	16	76	0	60	16	76	16	76

TABLE 2-continued

Complexity of $\frac{1}{8}$ resolution sub-pixel interpolation in TML5, TML6 and the method according to the invention. (Results shown separately for Preferred Method 1 and Preferred Method 2).								
Location	TML5		TML6		Preferred Method 1		Preferred Method 2	
	linear.	8-tap	linear.	8-tap	linear.	8-tap	linear.	8-tap
28, 30, 44, 46	32	152	0	60	16	60	16	60
Average	64	290.25	0	197.75	48	214.75	48	192.75

As can be seen from Table 2, the number of 8-tap filtering operations performed according to preferred methods 1 and 2 are, respectively, 26% and 34% lower than the number of 8-tap filtering operation performed in the sub-pixel value interpolation method of TML5. The number of linear operations is 25% lower, in both preferred method 1 and preferred method 2, compared with TML5, but this improvement is of lesser importance compared to the reduction in 8-tap filtering operations. It can further be seen that the direct interpolation method used in TML6 has a complexity comparable that of both preferred methods 1 and 2 when used to interpolate values for $\frac{1}{8}$ resolution sub-pixels.

In view of the foregoing description it will be evident to a person skilled in the art that various modifications may be made within the scope of the invention. While a number of preferred embodiments of the invention have been described in detail, it should be apparent that many modifications and variations thereto are possible, all of which fall within the true spirit and scope of the invention.

The invention claimed is:

1. A method for sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being arranged in rows and columns, the pixel and sub-pixel locations being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the method comprising:

interpolating a sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, according to a predetermined choice of a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $1/2$, $1/2$, and a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L, including zero, situated within a quadrant of the rectangular bounded region defined by corner pixels having co-ordinates $1/2$, $1/2$ and the nearest neighbouring pixel;

interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of both K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolating sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L,

using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent bounded rectangular regions.

2. A method according to claim 1, comprising using a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, wherein when the chosen weighted average is that involving the value of a nearest neighbouring pixel and the value of the sub-pixel situated at co-ordinates $1/2$, $1/2$, selecting the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the nearest-neighbouring pixel and the sub-pixel situated at co-ordinates $1/2$, $1/2$ to the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

3. A method according to claim 2, comprising using first and second weights with equal values when the nearest-neighbouring pixel second sub-pixel situated at co-ordinates $1/2$, $1/2$ are equidistant from the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

4. A method according to claim 1, comprising using a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, wherein when the chosen weighted average is that involving the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L, selecting the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the sub-pixels having co-ordinates with even values of both K and L to the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

5. A method according to claim 4, comprising using first and second weights with equal values when the sub-pixels having co-ordinates with even values of both K and L are equidistant from the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

6. A method according to claim 1, comprising interpolating sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels

having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an even value and L equal to an odd value is also required.

7. A method according to claim 1, comprising interpolating sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an odd value and L equal to an even value is also required.

8. A method according to claim 1, comprising interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to an odd value O and L equal to an even value E, not including zero or 2^N , by taking an average of the value of a first sub-pixel having co-ordinates with K equal to the even value O-1 and L equal to E and a second sub-pixel having co-ordinates with K equal to the even value O+1 and L equal to E.

9. A method according to claim 1, comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2 and L equal to zero.

10. A method according to claim 1, comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to zero.

11. A method according to claim 1, comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2 and L equal to 2^N .

12. A method according to claim 1, comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to 2^N .

13. A method according to claim 1, comprising interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to an even value E, not including zero or 2^N , and L equal to an odd value O, by taking an average of the value of a first sub-pixel having co-ordinates with K equal to E and L equal to the even value O-1 and a second sub-pixel having co-ordinates with K equal to E and L equal to the even value O+1.

14. A method according to claim 1, comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to zero and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

15. A method according to claim 1, comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

16. A method according to claim 1, comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 0 and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to zero and L equal to 2^N-2 .

17. A method according to claim 1, comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-2 .

18. A method according to claim 1, comprising interpolating a sub-pixel value for the sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N-1 , by taking a weighted average of the values of the four corner pixels that define the rectangular bounded region.

19. A method according to claim 1, comprising selecting a value for N from a list consisting of the values 2, 3, and 4.

20. A method for quarter resolution sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being arranged in rows and columns, the pixel and sub-pixel locations being representable mathematically within the rectangular bounded region using the co-ordinate notation K/4, L/4, K and L being positive integers having respective values between zero and 4, the method comprising:

interpolating a sub-pixel value for a sub-pixel having co-ordinates with both K and L equal to 1 or 3, according to a predetermined choice of a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates 2/4, 2/4, and a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with both K and L equal to zero, 2 or 4, situated within a quadrant of the rectangular bounded region defined by corner pixels having co-ordinates 2/4, 2/4 and the nearest neighbouring pixel;

interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to 2 and L equal zero and sub-pixels having co-ordinates with K equal to zero and L equal to 2, used in the interpolation of the sub-pixels having co-ordinates with both K and L equal to 1 or 3, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolating a sub-pixel value for the sub-pixel having co-ordinates with both K and L equal to 2, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with both K and L equal to 1 or 3, using a predetermined choice of either a weighted sum of the values of the sub-pixel having co-ordinates with K equal to 2 and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the value of the sub-pixel having co-ordinates with K equal to zero and L equal to 2 and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

21. A method for eighth resolution sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being arranged in rows and columns, the

pixel and sub-pixel locations being representable mathematically with the rectangular bounded region using the co-ordinate notation $K/8$, $L/8$, K and L being positive integers having respective values between zero and 8, the method comprising:

interpolating a sub-pixel value for a sub-pixel having co-ordinates with both K and L equal to 1, 3, 5 or 7, according to a predetermined choice of a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $4/8$, $4/8$, and a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with both K and L equal to zero, 2, 4, 6 or 8, situated within a quadrant of the rectangular bounded region defined by corner pixels having co-ordinates $4/8$, $4/8$ and the nearest neighbouring pixel;

interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to 2, 4 or 6 and L equal zero and sub-pixels having co-ordinates with K equal to zero and L equal to 2, 4 or 6, used in the interpolation of the sub-pixels having co-ordinates with both K and L equal to 1, 3, 5 or 7, using weighted sums of the values of pixels located in rows and columns respectively; and interpolating sub-pixel values for sub-pixels having co-ordinates with both K and L equal to 2, 4 or 6, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with both K and L equal to 1, 3, 5 or 7, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to 2, 4 or 6 and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to 2, 4 or 6 and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

22. An apparatus for sub-pixel value interpolation, the apparatus being operable to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being arranged in rows and columns, the pixel and sub-pixel locations being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the apparatus comprising:

circuitry operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L , according to a predetermined choice of a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $1/2$, $1/2$, and a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L , including zero, situated within a quadrant of the rectangular bounded region defined by corner pixels having co-ordinates $1/2$, $1/2$ and the nearest neighbouring pixel;

circuitry operable to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of both K and L , using

weighted sums of the values of pixels located in rows and columns respectively; and

circuitry operable to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of both K and L , used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L , using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent bounded rectangular regions.

23. An apparatus according to claim **22**, wherein the apparatus is operable to use a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L , wherein when the chosen weighted average is that involving the value of a nearest neighbouring pixel and the value of the sub-pixel situated at co-ordinates $1/2$, $1/2$, the apparatus is operable to select the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the nearest-neighbouring pixel and the sub-pixel situated at co-ordinates $1/2$, $1/2$ to the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

24. An apparatus according to claim **23**, wherein the apparatus is operable to use first and second weights with equal values when the nearest-neighbouring pixel and sub-pixel situated at co-ordinates $1/2$, $1/2$ are equidistant from the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

25. An apparatus according to claim **23**, wherein the apparatus is operable to use first and second weights with equal values when the sub-pixels having co-ordinates with even values of both K and L are equidistant from the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

26. An apparatus according to claim **22**, wherein the apparatus is operable to use a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L , wherein when the chosen weighted average is that involving the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L , the apparatus is operable to select the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the sub-pixels having co-ordinates with even values of both K and L to the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

27. A communications terminal comprising a video encoder according to claim **23**.

28. A communications terminal comprising a video decoder according to claim **26**.

29. An apparatus according to claim **22**, wherein the apparatus is operable to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of both K and L , used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L , using a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular

51

bounded regions when the value of a sub-pixel having co-ordinates with K equal to an even value and L equal to an odd value is also required.

30. An apparatus according to claim 22, wherein the apparatus is operable to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an odd value and L equal to an even value is also required.

31. An apparatus according to claim 22, wherein the apparatus is operable to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an odd value O and L equal to an even value E, not including zero or 2^N , by taking an average of the value of a first sub-pixel having co-ordinates with K equal to the even value O-1 and L equal to E and a second sub-pixel having co-ordinates with K equal to the even value O+1 and L equal to E.

32. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2 and L equal to zero.

33. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to zero.

34. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2 and L equal to zero.

35. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to 2^N .

36. An apparatus according to claim 22, wherein the apparatus is operable to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value E, not including zero or 2^N , and L equal to an odd value O, by taking an average of the value of a first sub-pixel having co-ordinates with K equal to E and L equal to the even value O-1 and a second sub-pixel having co-ordinates with K equal to E and L equal to the even value O+1.

52

37. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to zero and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

38. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

39. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 0 and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to zero and L equal to 2^N-2 .

40. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-2 .

41. An apparatus according to claim 22, wherein the apparatus is operable to interpolate a sub-pixel value for the sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N-1 , by taking a weighted average of the values of the four corner pixels that define the rectangular bounded region.

42. An apparatus according to claim 22, wherein N is set equal to 2.

43. An apparatus according to claim 22, wherein N is set equal to 3.

44. A video encoder comprising an apparatus for sub-pixel value interpolation according to claim 22.

45. A still image encoder comprising an apparatus for sub-pixel value interpolation according to claim 22.

46. A video decoder comprising an apparatus for sub-pixel value interpolation according to claim 22.

47. A communications terminal comprising a still image encoder according to claim 45.

48. A still image decoder comprising an apparatus for sub-pixel value interpolation according to claim 22.

49. A codec comprising a video encoder according to claim 44 and a video decoder according to claim 46.

50. A communications terminal comprising a still image decoder according to claim 48.

51. A codec comprising a still image encoder according to claim 45 and a still image decoder according to claim 48.

(21) Appl. No.: **11/839,205**

(57) **ABSTRACT**

(22) Filed: **Aug. 15, 2007**

A method of interpolation in video coding in which an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, is interpolated to generate values for sub-pixels at fractional horizontal and vertical locations, the method comprising:

METHOD FOR SUB-PIXEL VALUE INTERPOLATION

CROSS REFERENCE TO RELATED APPLICATIONS

This application is a continuation of, and claims priority to, U.S. application Ser. No. 11/090,717, filed Mar. 25, 2005, now allowed, which is a continuation of, and claims priority to, U.S. application Ser. No. 09/954,608, filed Sep. 17, 2001, now U.S. Pat. No. 6,950,469, all of which are incorporated by reference herein in their entirety.

The present invention relates to a method for sub-pixel value interpolation in the encoding and decoding of data. It relates particularly, but not exclusively, to encoding and decoding of digital video.

BACKGROUND OF THE INVENTION

Digital video sequences, like ordinary motion pictures recorded on film, comprise a sequence of still images, the illusion of motion being created by displaying the images one after the other at a relatively fast frame rate, typically 15 to 30 frames per second. Because of the relatively fast frame rate, images in consecutive frames tend to be quite similar and thus contain a considerable amount of redundant information. For example, a typical scene may comprise some stationary elements, such as background scenery, and some moving areas, which may take many different forms, for example the face of a newsreader, moving traffic and so on. Alternatively, the camera recording the scene may itself be moving, in which case all elements of the image have the same kind of motion. In many cases, this means that the overall change between one video frame and the next is rather small. Of course, this depends on the nature of the movement. For example, the faster the movement, the greater the change from one frame to the next. Similarly, if a scene contains a number of moving elements, the change from one frame to the next is likely to be greater than in a scene where only one element is moving.

It should be appreciated that each frame of a raw, that is uncompressed, digital video sequence comprises a very large amount of image information. Each frame of an uncompressed digital video sequence is formed from an array of image pixels. For example, in a commonly used digital video format, known as the Quarter Common Interchange Format (QCIF), a frame comprises an array of 176×144 pixels, in which case each frame has 25,344 pixels. In turn, each pixel is represented by a certain number of bits, which carry information about the luminance and/or colour content of the region of the image corresponding to the pixel. Commonly, a so-called YUV colour model is used to represent the luminance and chrominance content of the image. The luminance, or Y, component represents the intensity (brightness) of the image, while the colour content of the image is represented by two chrominance components, labelled U and V.

Colour models based on a luminance/chrominance representation of image content provide certain advantages compared with colour models that are based on a representation involving primary colours (that is Red, Green and Blue, RGB). The human visual system is more sensitive to intensity variations than it is to colour variations; YUV colour models exploit this property by using a lower spatial resolution for the chrominance components (U, V) than for the luminance component (Y). In this way the amount of information needed to code the colour information in an image can be reduced with an acceptable reduction in image quality.

The lower spatial resolution of the chrominance components is usually attained by sub-sampling. Typically, a block of 16×16 image pixels is represented by one block of 16×16 pixels comprising luminance information and the corresponding chrominance components are each represented by one block of 8×8 pixels representing an area of the image equivalent to that of the 16×16 pixels of the luminance component. The chrominance components are thus spatially sub-sampled by a factor of 2 in the x and y directions. The resulting assembly of one 16×16 pixel luminance block and two 8×8 pixel chrominance blocks is commonly referred to as a YUV macroblock, or macroblock, for short.

A QCIF image comprises 11×9 macroblocks. If the luminance blocks and chrominance blocks are represented with 8 bit resolution (that is by numbers in the range 0 to 255), the total number of bits required per macroblock is $(16 \times 16 \times 8) + 2 \times (8 \times 8 \times 8) = 3072$ bits. The number of bits needed to represent a video frame in QCIF format is thus $99 \times 3072 = 304,128$ bits. This means that the amount of data required to transmit/record/display a video sequence in QCIF format, represented using a YUV colour model, at a rate of 30 frames per second, is more than 9 Mbps (million bits per second). This is an extremely high data rate and is impractical for use in video recording, transmission and display applications because of the very large storage capacity, transmission channel capacity and hardware performance required.

If video data is to be transmitted in real-time over a fixed line network such as an ISDN (Integrated Services Digital Network) or a conventional PSTN (Public Service Telephone Network), the available data transmission bandwidth is typically of the order of 64 kbits/s. In mobile videotelephony, where transmission takes place at least in part over a radio communications link, the available bandwidth can be as low as 20 kbits/s. This means that a significant reduction in the amount of information used to represent video data must be achieved in order to enable transmission of digital video sequences over low bandwidth communication networks. For this reason video compression techniques have been developed which reduce the amount of information transmitted while retaining an acceptable image quality.

Video compression methods are based on reducing the redundant and perceptually irrelevant parts of video sequences. The redundancy in video sequences can be categorised into spatial, temporal and spectral redundancy. 'Spatial redundancy' is the term used to describe the correlation between neighbouring pixels within a frame. The term 'temporal redundancy' expresses the fact that the objects appearing in one frame of a sequence are likely to appear in subsequent frames, while 'spectral redundancy' refers to the correlation between different colour components of the same image.

Sufficiently efficient compression cannot usually be achieved by simply reducing the various forms of redundancy in a given sequence of images. Thus, most current video encoders also reduce the quality of those parts of the video sequence which are subjectively the least important. In addition, the redundancy of the compressed video bit-stream is itself reduced by means of efficient loss-less encoding. Typically, this is achieved using a technique known as 'variable length coding' (VLC).

Modern video compression standards, such as ITU-T recommendations H.261, H.263(+)(++), H.26L and the Motion Picture Experts Group recommendation MPEG-4 make use of 'motion compensated temporal prediction'. This is a form of temporal redundancy reduction in which the content of some (often many) frames in a video sequence is 'predicted'

from other frames in the sequence by tracing the motion of objects or regions of an image between frames.

Compressed images which do not make use of temporal redundancy reduction are usually called INTRA-coded or I-frames, whereas temporally predicted images are called INTER-coded or P-frames. In the case of INTER frames, the predicted (motion-compensated) image is rarely precise enough to represent the image content with sufficient quality, and therefore a spatially compressed prediction error (PE) frame is also associated with each INTER frame. Many video compression schemes can also make use of bi-directionally predicted frames, which are commonly referred to as B-pictures or B-frames. B-pictures are inserted between reference or so-called 'anchor' picture pairs (I or P frames) and are predicted from either one or both of the anchor pictures. B-pictures are not themselves used as anchor pictures, that is no other frames are predicted from them, and therefore, they can be discarded from the video sequence without causing deterioration in the quality of future pictures.

The different types of frame that occur in a typical compressed video sequence are illustrated in FIG. 3 of the accompanying drawings. As can be seen from the figure, the sequence starts with an INTRA or I frame 30. In FIG. 3, arrows 33 denote the 'forward' prediction process by which P-frames (labelled 34) are formed. The bi-directional prediction process by which B-frames (36) are formed is denoted by arrows 31a and 31b, respectively.

A schematic diagram of an example video coding system using motion compensated prediction is shown in FIGS. 1 and 2. FIG. 1 illustrates an encoder 10 employing motion compensation and FIG. 2 illustrates a corresponding decoder 20. The encoder 10 shown in FIG. 1 comprises a Motion Field Estimation block 11, a Motion Field Coding block 12, a Motion Compensated Prediction block 13, a Prediction Error Coding block 14, a Prediction Error Decoding block 15, a Multiplexing block 16, a Frame Memory 17, and an adder 19. The decoder 20 comprises a Motion Compensated Prediction block 21, a Prediction Error Decoding block 22, a Demultiplexing block 23 and a Frame Memory 24.

The operating principle of video coders using motion compensation is to minimise the amount of information in a prediction error frame $E_n(x,y)$, which is the difference between a current frame $I_n(x,y)$ being coded and a prediction frame $P_n(x,y)$. The prediction error frame is thus:

$$E_n(x,y) = I_n(x,y) - P_n(x,y). \quad (1)$$

The prediction frame $P_n(x,y)$ is built using pixel values of a reference frame $R_n(x,y)$, which is generally one of the previously coded and transmitted frames, for example the frame immediately preceding the current frame and is available from the Frame Memory 17 of the encoder 10. More specifically, the prediction frame $P_n(x,y)$ is constructed by finding so-called 'prediction pixels' in the reference frame $R_n(x,y)$ which correspond substantially with pixels in the current frame. Motion information, describing the relationship (e.g. relative location, rotation, scale etc.) between pixels in the current frame and their corresponding prediction pixels in the reference frame is derived and the prediction frame is constructed by moving the prediction pixels according to the motion information. In this way, the prediction frame is constructed as an approximate representation of the current frame, using pixel values in the reference frame. The prediction error frame referred to above therefore represents the difference between the approximate representation of the current frame provided by the prediction frame and the current frame itself. The basic advantage provided by video encoders that use motion compensated prediction arises from the fact

that a comparatively compact description of the current frame can be obtained by representing it in terms of the motion information required to form its prediction together with the associated prediction error information in the prediction error frame.

However, due to the very large number of pixels in a frame, it is generally not efficient to transmit separate motion information for each pixel to the decoder. Instead, in most video coding schemes, the current frame is divided into larger image segments S_k and motion information relating to the segments is transmitted to the decoder. For example, motion information is typically provided for each macroblock of a frame and the same motion information is then used for all pixels within the macroblock. In some video coding standards, such as H.26L, a macroblock can be divided into smaller blocks, each smaller block being provided with its own motion information.

The motion information usually takes the form of motion vectors $[\Delta x(x,y), \Delta y(x,y)]$. The pair of numbers $\Delta x(x,y)$ and $\Delta y(x,y)$ represents the horizontal and vertical displacements of a pixel at location (x,y) in the current frame $I_n(x,y)$ with respect to a pixel in the reference frame $R_n(x,y)$. The motion vectors $[\Delta x(x,y), \Delta y(x,y)]$ are calculated in the Motion Field Estimation block 11 and the set of motion vectors of the current frame $[\Delta x(\cdot), \Delta y(\cdot)]$ is referred to as the motion vector field.

Typically, the location of a macroblock in a current video frame is specified by the (x,y) co-ordinate of its upper left-hand corner. Thus, in a video coding scheme in which motion information is associated with each macroblock of a frame, each motion vector describes the horizontal and vertical displacement $\Delta x(x,y)$ and $\Delta y(x,y)$ of a pixel representing the upper left-hand corner of a macroblock in the current frame $I_n(x,y)$ with respect to a pixel in the upper left-hand corner of a substantially corresponding block of prediction pixels in the reference frame $R_n(x,y)$ (as shown in FIG. 4b).

Motion estimation is a computationally intensive task. Given a reference frame $R_n(x,y)$ and, for example, a square macroblock comprising $N \times N$ pixels in a current frame (as shown in FIG. 4a), the objective of motion estimation is to find an $N \times N$ pixel block in the reference frame that matches the characteristics of the macroblock in the current picture according to some criterion. This criterion can be, for example, a sum of absolute differences (SAD) between the pixels of the macroblock in the current frame and the block of pixels in the reference frame with which it is compared. This process is known generally as 'block matching'. It should be noted that, in general, the geometry of the block to be matched and that in the reference frame do not have to be the same, as real-world objects can undergo scale changes, as well as rotation and warping. However, in current international video coding standards, only a translational motion model is used (see below) and thus fixed rectangular geometry is sufficient.

Ideally, in order to achieve the best chance of finding a match, the whole of the reference frame should be searched. However, this is impractical as it imposes too high a computational burden on the video encoder. Instead, the search region is restricted to region $[-p,p]$ around the original location of the macroblock in the current frame, as shown in FIG. 4c.

In order to reduce the amount of motion information to be transmitted from the encoder 10 to the decoder 20, the motion vector field is coded in the Motion Field Coding block 12 of the encoder 10, by representing it with a motion model. In this process, the motion vectors of image segments are re-expressed using certain predetermined functions or, in other words, the motion vector field is represented with a model.

5

Almost all currently used motion vector field models are additive motion models, complying with the following general formula:

$$\Delta x(x, y) = \sum_{i=0}^{N-1} a_i f_i(x, y) \quad (2)$$

$$\Delta y(x, y) = \sum_{i=0}^{M-1} b_i g_i(x, y) \quad (3)$$

where coefficients a_i and b_i are called motion coefficients. The motion coefficients are transmitted to the decoder **20** (information stream **2** in FIGS. **1** and **2**). Functions f_i and g_i are called motion field basis functions, and are known both to the encoder and decoder. An approximate motion vector field ($\hat{\Delta}x(x, y), \hat{\Delta}y(x, y)$) can be constructed using the coefficients and the basis functions. As the basis functions are known to (that is stored in) both the encoder **10** and the decoder **20**, only the motion coefficients need to be transmitted to the encoder, thus reducing the amount of information required to represent the motion information of the frame.

The simplest motion model is the translational motion model which requires only two coefficients to describe the motion vectors of each segment. The values of motion vectors are given by:

$$\Delta x(x, y) = a_0$$

$$\Delta y(x, y) = b_0 \quad (4)$$

This model is widely used in various international standards (ISO MPEG-1, MPEG-2, MPEG-4, ITU-T Recommendations H.261 and H.263) to describe the motion of 16×16 and 8×8 pixel blocks. Systems which use a translational motion model typically perform motion estimation at full pixel resolution or some integer fraction of full pixel resolution, for example at half or one quarter pixel resolution.

The prediction frame $P_n(x, y)$ is constructed in the Motion Compensated Prediction block **13** in the encoder **10**, and is given by:

$$P_n(x, y) = R_n[x + \hat{\Delta}x(x, y), y + \hat{\Delta}y(x, y)] \quad (5)$$

In the Prediction Error Coding block **14**, the prediction error frame $E_n(x, y)$ is typically compressed by representing it as a finite series (transform) of some 2-dimensional functions. For example, a 2-dimensional Discrete Cosine Transform (DCT) can be used. The transform coefficients are quantised and entropy (for example Huffman) coded before they are transmitted to the decoder (information stream **1** in FIGS. **1** and **2**). Because of the error introduced by quantisation, this operation usually produces some degradation (loss of information) in the prediction error frame $E_n(x, y)$. To compensate for this degradation, the encoder **10** also comprises a Prediction Error Decoding block **15**, where a decoded prediction error frame $\hat{E}_n(x, y)$ is constructed using the transform coefficients. This locally decoded prediction error frame is added to the prediction frame $P_n(x, y)$ in the adder **19** and the resulting decoded current frame $\hat{I}_n(x, y)$ is stored in the Frame Memory **17** for further use as the next reference frame $R_{n+1}(x, y)$.

The information stream **2** carrying information about the motion vectors is combined with information about the prediction error in multiplexer **16** and an information stream **3** containing typically at least those two types of information is sent to the decoder **20**.

6

The operation of a corresponding video decoder **20** will now be described.

The Frame Memory **24** of the decoder **20** stores a previously reconstructed reference frame $R_n(x, y)$. The prediction frame $P_n(x, y)$ is constructed in the Motion Compensated Prediction block **21** of the decoder **20** according to equation 5, using received motion coefficient information and pixel values of the previously reconstructed reference frame $R_n(x, y)$. The transmitted transform coefficients of the prediction error frame $E_n(x, y)$ are used in the Prediction Error Decoding block **22** to construct the decoded prediction error frame $\hat{E}_n(x, y)$. The pixels of the decoded current frame $\hat{I}_n(x, y)$ are then reconstructed by adding the prediction frame $P_n(x, y)$ and the decoded prediction error frame $\hat{E}_n(x, y)$:

$$\hat{I}_n(x, y) = P_n(x, y) + \hat{E}_n(x, y) = R_n[x + \hat{\Delta}x(x, y), y + \hat{\Delta}y(x, y)] + \hat{E}_n(x, y) \quad (6)$$

This decoded current frame may be stored in the Frame Memory **24** as the next reference frame $R_{n+1}(x, y)$.

In the description of motion compensated encoding and decoding of digital video presented above, the motion vector $[\Delta x(x, y), \Delta y(x, y)]$ describing the motion of a macroblock in the current frame with respect to the reference frame $R_n(x, y)$ can point to any of the pixels in the reference frame. This means that motion between frames of a digital video sequence can only be represented at a resolution which is determined by the image pixels in the frame (so-called full pixel resolution). Real motion, however, has arbitrary precision, and thus the system described above can only provide approximate modelling of the motion between successive frames of a digital video sequence. Typically, modelling of motion between video frames with full pixel resolution is not sufficiently accurate to allow efficient minimisation of the prediction error (PE) information associated with each macroblock/frame. Therefore, to enable more accurate modelling of real motion and to help reduce the amount of PE information that must be transmitted from encoder to decoder, many video coding standards, such as H.263(+) and H.26L, allow motion vectors to point 'in between' image pixels. In other words, the motion vectors can have 'sub-pixel' resolution. Allowing motion vectors to have sub-pixel resolution adds to the complexity of the encoding and decoding operations that must be performed, so it is still advantageous to limit the degree of spatial resolution a motion vector may have. Thus, video coding standards, such as those previously mentioned, typically only allow motion vectors to have full-, half- or quarter-pixel resolution.

Motion estimation with sub-pixel resolution is usually performed as a two-stage process, as illustrated in FIG. **5**, for a video coding scheme which allows motion vectors to have full- or half-pixel resolution. In the first step, a motion vector having full-pixel resolution is determined using any appropriate motion estimation scheme, such as the block-matching process described in the foregoing. The resulting motion vector, having full-pixel resolution is shown in FIG. **5**.

In the second stage, the motion vector determined in the first stage is refined to obtain the desired half-pixel resolution. In the example illustrated in FIG. **5**, this is done by forming eight new search blocks of 16×16 pixels, the location of the top-left corner of each block being marked with an X in FIG. **5**. These locations are denoted as $[\Delta x + m/2, \Delta y + n/2]$, where m and n can take the values $-1, 0$ and $+1$, but cannot be zero at the same time. As only the pixel values of original image pixels are known, the values (for example luminance and/or chrominance values) of the sub-pixels residing at half-pixel locations must be estimated for each of the eight new search blocks, using some form of interpolation scheme.

Having interpolated the values of the sub-pixels at half-pixel resolution, each of the eight search blocks is compared with the macroblock whose motion vector is being sought. As in the block matching process performed in order to determine the motion vector with full pixel resolution, the macroblock is compared with each of the eight search blocks according to some criterion, for example a SAD. As a result of the comparisons, a minimum SAD value will generally be obtained. Depending on the nature of the motion in the video sequence, this minimum value may correspond to the location specified by the original motion vector (having full-pixel resolution), or it may correspond to a location having a half-pixel resolution. Thus, it is possible to determine whether a motion vector should point to a full-pixel or sub-pixel location and if sub-pixel resolution is appropriate, to determine the correct sub-pixel resolution motion vector. It should also be appreciated that the scheme just described can be extended to other sub-pixel resolutions (for example, one-quarter-pixel resolution) in an entirely analogous fashion.

In practice, the estimation of a sub-pixel value in the reference frame is performed by interpolating the value of the sub-pixel from surrounding pixel values. In general, interpolation of a sub-pixel value $F(x,y)$ situated at a non-integer location $(x,y)=(n+\Delta x, m+\Delta y)$, can be formulated as a two-dimensional operation, represented mathematically as:

$$F(x, y) = \sum_{k=-K}^{K-1} \sum_{l=-L}^{L-1} f(k+K, l+L) F(n+k, m+l) \quad (7)$$

where $f(k,l)$ are filter coefficients and n and m are obtained by truncating x and y , respectively, to integer values. Typically, the filter coefficients are dependent on the x and y values and the interpolation filters are usually so-called 'separable filters', in which case sub-pixel value $F(x,y)$ can be calculated as follows:

$$F(x, y) = \sum_{k=-K}^{K-1} f(k+K) \sum_{l=-K}^{K-1} f(l+K) F(n+k, m+l) \quad (8)$$

The motion vectors are calculated in the encoder. Once the corresponding motion coefficients are transmitted to the decoder, it is a straightforward matter to interpolate the required sub-pixels using an interpolation method identical to that used in the encoder. In this way, a frame following a reference frame in the Frame Memory 24, can be reconstructed from the reference frame and the motion vectors.

The simplest way of applying sub-pixel value interpolation in a video coder is to interpolate each sub-pixel value every time it is needed. However, this is not an efficient solution in a video encoder, because it is likely that the same sub-pixel value will be required several times and thus calculations to interpolate the same sub-pixel value will be performed multiple times. This results in an unnecessary increase of computational complexity/burden in the encoder.

An alternative approach, which limits the complexity of the encoder, is to pre-calculate and store all sub-pixel values in a memory associated with the encoder. This solution is called interpolation 'before-hand' interpolation hereafter in this document. While limiting complexity, before-hand interpolation has the disadvantage of increasing memory usage by a large margin. For example, if the motion vector accuracy is one quarter pixel in both horizontal and vertical dimensions,

storing pre-calculated sub-pixel values for a complete image results in a memory usage that is 16 times that required to store the original, non-interpolated image. In addition, it involves the calculation of some sub-pixels which might not actually be required in calculating motion vectors in the encoder. Before-hand interpolation is also particularly inefficient in a video decoder, as the majority of pre-calculated sub-pixel values will never be required by the decoder. Thus, it is advantageous not to use pre-calculation in the decoder.

So-called 'on-demand' interpolation can be used to reduce memory requirements in the encoder. For example, if the desired pixel precision is quarter pixel resolution, only sub-pixels at one half unit resolution are interpolated before-hand for the whole frame and stored in the memory. Values of one-quarter pixel resolution sub-pixels are only calculated during the motion estimation/compensation process as and when it is required. In this case memory usage is only 4 times that required to store the original, non-interpolated image.

It should be noted that when before-hand interpolation is used, the interpolation process constitutes only a small fraction of the total encoder computational complexity/burden, since every pixel is interpolated just once. Therefore, in the encoder, the complexity of the interpolation process itself is not very critical when before-hand sub-pixel value interpolation is used. On the other hand, on-demand interpolation poses a much higher computational burden on the encoder, since sub-pixels may be interpolated many times. Hence the complexity of interpolation process, which may be considered in terms of the number of computational operations or operational cycles that must be performed in order to interpolate the sub-pixel values, becomes an important consideration.

In the decoder, the same sub-pixel values are used a few times at most and some are not needed at all. Therefore, in the decoder it is advantageous not to use before-hand interpolation at all, that is, it is advantageous not to pre-calculate any sub-pixel values.

Two interpolation schemes have been developed as part of the work ongoing in the ITU-Telecommunications Standardization Sector, Study Group 16, Video Coding Experts Group (VCEG), Questions 6 and 15. These approaches were proposed for incorporation into ITU-T recommendation H.26L and have been implemented in test models (TML) for the purposes of evaluation and further development. The test model corresponding to Question 15 is referred to as Test Model 5 (TML5), while that resulting from Question 6 is known as Test Model 6 (TML6). The interpolation schemes proposed in both TML5 and TML6 will now be described.

Throughout the description of the sub-pixel value interpolation scheme used in test model TML5, reference will be made to FIG. 12a, which defines a notation for describing pixel and sub-pixel locations specific to TML5. A separate notation, defined in FIG. 13a, will be used in the discussion of the sub-pixel value interpolation scheme used in TML6. A still further notation, illustrated in FIG. 14a, will be used later in the text in connection with the sub-pixel value interpolation method according to the invention. It should be appreciated that the three different notations used in the text are intended to assist in the understanding of each interpolation method and to help distinguish differences between them. However, in all three figures, the letter A is used to denote original image pixels (full pixel resolution). More specifically, the letter A represents the location of pixels in the image data representing a frame of a video sequence, the pixel values of pixels A being either received as current frame $I_n(x,y)$ from a video source, or reconstructed and stored as a reference frame $R_n(x,y)$ in the Frame Memory 17, 24 of the encoder 10 or the

decoder 20. All other letters represent sub-pixel locations, the values of the sub-pixels situated at the sub-pixel locations being obtained by interpolation.

Certain other terms will also be used in a consistent manner throughout the text to identify particular pixel and sub-pixel locations. These are as follows:

The term 'unit horizontal location' is used to describe the location of any sub-pixel that is constructed in a column of the original image data. Sub-pixels c and e in FIGS. 12a and 13a, as well as sub-pixels b and e in FIG. 14a have unit horizontal locations.

The term 'unit vertical location' is used to describe any sub-pixel that is constructed in a row of the original image data. Sub-pixels b and d in FIGS. 12a and 13a as well as sub-pixels b and d in FIG. 14a have unit vertical locations.

By definition, pixels A have unit horizontal and unit vertical locations.

The term 'half horizontal location' is used to describe the location of any sub-pixel that is constructed in a column that lies at half pixel resolution. Sub-pixels b, c, and e shown in FIGS. 12a and 13a fall into this category, as do sub-pixels b, c and f in FIG. 14a. In a similar manner, the term 'half vertical location' is used to describe the location of any sub-pixel that is constructed in a row that lies at half-pixel resolution, such as sub-pixels c and d in FIGS. 12a and 13a, as well as sub-pixels b, c and g in FIG. 14a.

Furthermore, the term 'quarter horizontal location' refers to any sub-pixel that is constructed in a column which lies at quarter-pixel resolution, such as sub-pixels d and e in FIG. 12a, sub-pixels d and g in FIG. 13a and sub-pixels d, g and h in FIG. 14a. Analogously, the term 'quarter vertical location' refers to sub-pixels that are constructed in a row which lies at quarter-pixel resolution. In FIG. 12a, sub-pixels e and f fall into this category, as do sub-pixels e, f and g in FIG. 13a and sub-pixels e, f and h in FIG. 14a.

The definition of each of the terms described above is shown by 'envelopes' drawn on the corresponding figures.

It should further be noted that it is often convenient to denote a particular pixel with a two-dimensional reference. In this case, the appropriate two-dimensional reference can be obtained by examining the intersection of the envelopes in FIGS. 12a, 13a and 14a. Applying this principle, pixel d in FIG. 12a, for example, has a half horizontal and half vertical location and sub-pixel e has a unit horizontal and quarter vertical location. In addition, and for ease of reference, sub-pixels that reside at half unit horizontal and unit vertical locations, unit horizontal and half unit vertical locations as well as half unit horizontal and half unit vertical locations, will be referred to as $\frac{1}{2}$ resolution sub-pixels. Sub-pixels which reside at any quarter unit horizontal and/or quarter unit vertical location will be referred to as $\frac{1}{4}$ resolution sub-pixels.

It should also be noted that in the descriptions of the two test models and in the detailed description of the invention itself, it will be assumed that pixels have a minimum value of 0 and a maximum value of $2^n - 1$ where n is the number of bits reserved for a pixel value. The number of bits is typically 8. After a sub-pixel has been interpolated, if the value of that interpolated sub-pixel exceeds the value of $2^n - 1$, it is restricted to the range of $[0, 2^n - 1]$, i.e. values lower than the minimum allowed value will become the minimum value (0) and values larger than the maximum will become maximum value ($2^n - 1$). This operation is called clipping.

The sub-pixel value interpolation scheme according to TML5 will now be described in detail with reference to FIGS. 12a, 12b and 12c.

1. The value for the sub-pixel at half unit horizontal and unit vertical location, that is $\frac{1}{2}$ resolution sub-pixel b in FIG. 12a, is calculated using a 6-tap filter. The filter interpolates a value for $\frac{1}{2}$ resolution sub-pixel b based upon the values of the 6 pixels (A_1 to A_6) situated in a row at unit horizontal locations and unit vertical locations symmetrically about b, as shown in FIG. 12b, according to the formula $b = (A_1 - 5A_2 + 20A_3 + 20A_4 - 5A_5 + A_6 + 16)/32$. The operator / denotes division with truncation. The result is clipped to lie in the range $[0, 2^n - 1]$.

2. Values for the $\frac{1}{2}$ resolution sub-pixels labelled c are calculated using the same six tap filter as used in step 1 and the six nearest pixels or sub-pixels (A or b) in the vertical direction. Referring now to FIG. 12c, the filter interpolates a value for the $\frac{1}{2}$ resolution sub-pixel c located at unit horizontal and half vertical location based upon the values of the 6 pixels (A_1 to A_6) situated in a column at unit horizontal locations and unit vertical locations symmetrically about c, according to the formula $c = (A_1 - 5A_2 + 20A_3 + 20A_4 - 5A_5 + A_6 + 16)/32$. Similarly, a value for the $\frac{1}{2}$ resolution sub-pixel c at half horizontal and half vertical location is calculated according to $c = (b_1 - 5b_2 + 20b_3 + 20b_4 - 5b_5 + b_6 + 16)/32$. Again, the operator / denotes division with truncation. The values calculated for the c sub-pixels are further clipped to lie in the range $[0, 2^n - 1]$.

At this point in the interpolation process the values of all $\frac{1}{2}$ resolution sub-pixels have been calculated and the process proceeds to the calculation of $\frac{1}{4}$ resolution sub-pixel values.

3. Values for the $\frac{1}{4}$ resolution sub-pixels labelled d are calculated using linear interpolation and the values of the nearest pixels and/or $\frac{1}{2}$ resolution sub-pixels in the horizontal direction. More specifically, values for $\frac{1}{4}$ resolution sub-pixels d located at quarter horizontal and unit vertical locations, are calculated by taking the average of the immediately neighbouring pixel at unit horizontal and unit vertical location (pixel A) and the immediately neighbouring $\frac{1}{2}$ resolution sub-pixel at half horizontal and unit vertical location (sub-pixel b), i.e. according to $d = (A + b)/2$. Values for $\frac{1}{4}$ resolution sub-pixels d located at quarter horizontal and half vertical locations, are calculated by taking the average of the immediately neighbouring $\frac{1}{2}$ resolution sub-pixels c which lie at unit horizontal and half vertical location and half horizontal and half vertical locations respectively, i.e. according to $d = (c_1 + c_2)/2$. Again operator / indicates division with truncation.

4. Values for the $\frac{1}{4}$ resolution sub-pixels labelled e are calculated using linear interpolation and the values of the nearest pixels and/or $\frac{1}{2}$ resolution sub-pixels in the vertical direction. In particular, $\frac{1}{4}$ resolution sub-pixels e at unit horizontal and quarter vertical locations are calculated by taking the average of the immediately neighbouring pixel at unit horizontal and unit vertical location (pixel A) and the immediately neighbouring sub-pixel at unit horizontal and half vertical location (sub-pixel c) according to $e = (A + c)/2$. $\frac{1}{4}$ resolution sub-pixels e_3 at half horizontal and quarter vertical locations are calculated by taking the average of the immediately neighbouring sub-pixel at half horizontal and unit vertical location (sub-pixel b) and the immediately neighbouring sub-pixel at half horizontal and half vertical location (sub-pixel c), according to $e = (b + c)/2$. Furthermore, $\frac{1}{4}$ resolution sub-pixels e at quarter horizontal and quarter vertical locations are calculated by taking the average of the immediately neighbouring sub-pixels at quarter horizontal and unit vertical location and the corresponding sub-pixel at quarter horizontal and half vertical location (sub-pixels d), according to $e = (d_1 + d_2)/2$. Once more, operator / indicates division with truncation.

11

5. The value for $\frac{1}{4}$ resolution sub-pixel f is interpolated by averaging the values of the 4 closest pixels values at unit horizontal and vertical locations, according to $f=(A_1+A_2+A_3+A_4+2)/4$, where pixels A_1, A_2, A_3 and A_4 are the four nearest original pixels.

A disadvantage of TML5 is that the decoder is computationally complex. This results from the fact that TML5 uses an approach in which interpolation of $\frac{1}{4}$ resolution sub-pixel values depends upon the interpolation of $\frac{1}{2}$ resolution sub-pixel values. This means that in order to interpolate the values of the $\frac{1}{4}$ resolution sub-pixels, the values of the $\frac{1}{2}$ resolution sub-pixels from which they are determined must be calculated first. Furthermore, since the values of some of the $\frac{1}{4}$ resolution sub-pixels depend upon the interpolated values obtained for other $\frac{1}{4}$ resolution sub-pixels, truncation of the $\frac{1}{4}$ resolution sub-pixel values has a deleterious effect on the precision of some of the $\frac{1}{4}$ resolution sub-pixel values. Specifically, the $\frac{1}{4}$ resolution sub-pixel values are less precise than they would be if calculated from values that had not been truncated and clipped. Another disadvantage of TML5 is that it is necessary to store the values of the $\frac{1}{2}$ resolution sub-pixels in order to interpolate the $\frac{1}{4}$ resolution sub-pixel values. Therefore, excess memory is required to store a result which is not ultimately required.

The sub-pixel value interpolation scheme according to TML6, referred to herein as direct interpolation, will now be described. In the encoder the interpolation method according to TML6 works like the previously described TML5 interpolation method, except that maximum precision is retained throughout. This is achieved by using intermediate values which are neither rounded nor clipped. A step-by-step description of interpolation method according to TML6 as applied in the encoder is given below with reference to FIGS. 13a, 13b and 13c.

1. The value for the sub-pixel at half unit horizontal and unit vertical location, that is $\frac{1}{2}$ resolution sub-pixel b in FIG. 13a, is obtained by first calculating an intermediate value b using a six tap filter. The filter calculates b based upon the values of the 6 pixels (A_1 to A_6) situated in a row at unit horizontal locations and unit vertical locations symmetrically about b, as shown in FIG. 13b, according to the formula $b=(A_1-5A_2+20A_3+20A_4-5A_5+A_6)$. The final value of b is then calculated as $b=(b+16)/32$ and is clipped to lie in the range $[0, 2^n-1]$. As before, the operator / denotes division with truncation.
2. Values for the $\frac{1}{2}$ resolution sub-pixels labelled c are obtained by first calculating intermediate values c. Referring to FIG. 13c, an intermediate value c for the $\frac{1}{2}$ resolution sub-pixel c located at unit horizontal and half vertical location is calculated based upon the values of the 6 pixels (A_1 to A_6) situated in a column at unit horizontal locations and unit vertical locations symmetrically about c, according to the formula $c=(A_1-5A_2+20A_3+20A_4-5A_5+A_6)$. The final value for the $\frac{1}{2}$ resolution sub-pixel c located at unit horizontal and half vertical location is then calculated according to $c=(c+16)/32$. Similarly, an intermediate value c for the $\frac{1}{2}$ resolution sub-pixel c at half horizontal and half vertical location is calculated according to $c=(b_1-5b_2+20b_3+20b_4-5b_5+b_6)$. A final value for this $\frac{1}{2}$ resolution sub-pixel is then calculated according to $(c+512)/1024$. Again, the operator / denotes division with truncation and the values calculated for $\frac{1}{2}$ resolution sub-pixels c are further clipped to lie in the range $[0, 2^n-1]$.
3. Values for the $\frac{1}{4}$ resolution sub-pixels labelled d are calculated as follows. Values for $\frac{1}{4}$ resolution sub-pixels d located at quarter horizontal and unit vertical locations, are calculated from the value of the immediately neighbouring

12

pixel at unit horizontal and unit vertical location (pixel A) and the intermediate value b calculated in step (1) for the immediately neighbouring $\frac{1}{2}$ resolution sub-pixel at half horizontal and unit vertical location ($\frac{1}{2}$ resolution sub-pixel b), according to $d=(32A+b+32)/64$. Values for $\frac{1}{4}$ resolution sub-pixels d located at quarter horizontal and half vertical locations, are interpolated using the intermediate values c calculated for the immediately neighbouring $\frac{1}{2}$ resolution sub-pixels c which lie at unit horizontal and half vertical location and half horizontal and half vertical locations respectively, according to $d=(32c_1+c_2+1024)/2048$. Again operator / indicates division with truncation and the finally obtained $\frac{1}{4}$ resolution sub-pixel values d are clipped to lie in the range $[0, 2^n-1]$.

4. Values for the $\frac{1}{4}$ resolution sub-pixels labelled e are calculated as follows. Values for $\frac{1}{4}$ resolution sub-pixels e located at unit horizontal and quarter vertical locations are calculated from the value of the immediately neighbouring pixel at unit horizontal and unit vertical location (pixel A) and the intermediate value c calculated in step (2) for the immediately neighbouring $\frac{1}{2}$ resolution sub-pixel at unit horizontal and half vertical location, according to $e=(32A+c+32)/64$. Values for $\frac{1}{4}$ resolution sub-pixels e located at half horizontal and quarter vertical locations are calculated from the intermediate value b calculated in step (1) for the immediately neighbouring $\frac{1}{2}$ resolution sub-pixel at half horizontal and unit vertical location and the intermediate value c calculated in step (2) for the immediately neighbouring $\frac{1}{2}$ resolution sub-pixel at half horizontal and half vertical location, according to $e=(32b+c+1024)/2048$. Once more, operator / indicates division with truncation and the finally obtained $\frac{1}{4}$ resolution sub-pixel values e are clipped to lie in the range $[0, 2^n-1]$.
5. Values for $\frac{1}{4}$ resolution sub-pixels labelled g are computed using the value of the nearest original pixel A and the intermediate values of the three nearest neighbouring $\frac{1}{2}$ resolution sub-pixels, according to $g=(1024A+32b+32c_1+c_2+2048)/4096$. As before, operator / indicates division with truncation and the finally obtained for $\frac{1}{4}$ resolution sub-pixel values g are clipped to lie in the range $[0, 2^n-1]$.
6. The value for $\frac{1}{4}$ resolution sub-pixel f is interpolated by averaging the values of the 4 closest pixels at unit horizontal and vertical locations, according to $f=(A_1+A_2+A_3+A_4+2)/4$, where the locations of pixels A_1, A_2, A_3 and A_4 are the four nearest original pixels.

In the decoder, sub-pixel values can be obtained directly by applying 6-tap filters in horizontal and vertical directions. In the case of $\frac{1}{4}$ sub-pixel resolution, referring to FIG. 13a, the filter coefficients applied to pixels and sub-pixels at unit vertical location are $[0, 0, 64, 0, 0, 0]$ for a set of six pixels A, $[1, -5, 52, 20, -5, 1]$ for a set of six sub-pixels d, $[2, -10, 40, 40, -10, 2]$ for a set of six sub-pixels b, and $[1, -5, 20, 52, -5, 1]$ for a set of six sub-pixels c. These filter coefficients are applied to respective sets of pixels or sub-pixels in the same row as the sub-pixel values being interpolated.

After applying the filters in the horizontal and vertical directions, interpolated value c is normalized according to $c=(c+2048)/4096$ and clipped to lie in the range $[0, 2^n-1]$. When a motion vector points to an integer pixel position in either the horizontal or vertical direction, many zero coefficients are used. In a practical implementation of TML6, different branches are used in the software which are optimised for the different sub-pixel cases so that there are no multiplications by zero coefficients.

It should be noted that in TML6, $\frac{1}{4}$ resolution sub-pixel values are obtained directly using the intermediate values referred to above and are not derived from rounded and

13

clipped values for $\frac{1}{2}$ resolution sub-pixels. Therefore, in obtaining the $\frac{1}{4}$ resolution sub-pixel values, it is not necessary to calculate final values for any of the $\frac{1}{2}$ resolution sub-pixels. Specifically, it is not necessary to carry out the truncation and clipping operations associated with the calculation of final values for the $\frac{1}{2}$ resolution sub-pixels. Neither is it necessary to have stored final values for $\frac{1}{2}$ resolution sub-pixels for use in the calculation of the $\frac{1}{4}$ resolution sub-pixel values. Therefore TML6 is computationally less complex than TML5, as fewer truncating and clipping operations are required. However, a disadvantage of TML6 is that high precision arithmetic is required both in the encoder and in the decoder. High precision interpolation requires more silicon area in ASICs and requires more computations in some CPUs. Furthermore, implementation of direct interpolation as specified in TML6 in an on-demand fashion has a high memory requirement. This is an important factor, particularly in embedded devices.

In view of the previously presented discussion, it should be appreciated that due to the different requirements of the video encoder and decoder with regard to sub-pixel interpolation, there exists a significant problem in developing a method of sub-pixel value interpolation capable of providing satisfactory performance in both the encoder and decoder. Furthermore, neither of the current test models (TML5, TML6) described in the foregoing can provide a solution that is optimum for application in both encoder and decoder.

SUMMARY OF THE INVENTION

According to a first aspect of the invention there is provided method of interpolation in video coding in which an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, is interpolated to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $\frac{1}{2}^x$, where x is a positive integer having a maximum value N, the method comprising:

- a) when values for sub-pixels at $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical locations are required, interpolating such values directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) when values for sub-pixels at $\frac{1}{2}^{N-1}$ unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical locations are required, interpolating such values directly using a choice of a first weighted sum of values for sub-pixels residing at $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical locations and a second weighted sum of values for sub-pixels residing at unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical locations, the first and second weighted sums of values being calculated according to step (a); and
- c) when a value for a sub-pixel situated at a $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical location is required, interpolating such a value by taking a weighted average of the value of a first sub-pixel or pixel situated at a $\frac{1}{2}^{N-m}$ unit horizontal and $\frac{1}{2}^{N-n}$ unit vertical location and the value of a second sub-pixel or pixel located at a $\frac{1}{2}^{N-p}$ unit horizontal and $\frac{1}{2}^{N-q}$ unit vertical location, variables m, n, p and q taking integer values in the range 1 to N such that the first and second sub-pixels or pixels are located diagonally with respect to the sub-pixel at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical location.

Preferably a first and a second weight are used in the weighted average referred to in (c), the relative magnitudes of the weights being inversely proportional to the (straight-line

14

diagonal) proximity of the first and the second sub-pixel or pixel to the sub-pixel at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical location.

In a situation where the first and the second sub-pixel or pixel are symmetrically located with respect to (equidistant from) the sub-pixel at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical location, the first and second weights may have equal values.

The first weighted sum of values for sub-pixels residing at $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical locations in step b) may be used when a sub-pixel at $\frac{1}{2}^{N-1}$ unit horizontal and $\frac{1}{2}^N$ unit vertical location is required.

The second weighted sum of values for sub-pixels residing at unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical locations in step b) may be used when a sub-pixel at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location is required.

In one embodiment, when values for sub-pixels at $\frac{1}{2}^N$ unit horizontal and unit vertical locations, and $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical locations are required, such values are interpolated by taking the average of the values of a first pixel or sub-pixel located at a vertical location corresponding to that of the sub-pixel being calculated and unit horizontal location and a second pixel or sub-pixel located at a vertical location corresponding to that of the sub-pixel being calculated and $\frac{1}{2}^{N-1}$ unit horizontal location.

When values for sub-pixels at unit horizontal and $\frac{1}{2}^N$ unit vertical locations, and $\frac{1}{2}^{N-1}$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations are required, they may be interpolated by taking the average of the values of a first pixel or sub-pixel located at a horizontal location corresponding to that of the sub-pixel being calculated and unit vertical location and a second pixel or sub-pixel located at a horizontal location corresponding to that of the sub-pixel being calculated and $\frac{1}{2}^{N-1}$ unit vertical location.

Values for sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations may be interpolated by taking the average of values of a pixel located at a unit horizontal and unit vertical location, and a sub-pixel located at a $\frac{1}{2}^{N-1}$ unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location.

Values for sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations may be interpolated by taking the average of values of a sub-pixel located at a $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical location, and a sub-pixel located at a unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location.

Values for half of the sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations may be interpolated by taking the average of a first pair of values of a sub-pixel located at a $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical location, and a sub-pixel located at a unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location and values for the other half of the sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations are interpolated by taking the average of a second pair of values of a pixel located at a unit horizontal and unit vertical location, and a sub-pixel located at a $\frac{1}{2}^{N-1}$ unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location.

Values for sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations are alternately interpolated for one such sub-pixel by taking the average of a first pair of values of a sub-pixel located at a $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical location, and a sub-pixel located at a unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location and values and for a neighbouring such sub-pixel by taking the average of a second pair of values of a pixel located at a unit horizontal and unit vertical location, and a sub-pixel located at a $\frac{1}{2}^{N-1}$ unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location.

The sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations may be alternately interpolated in a horizontal direction.

15

The sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations may be alternately interpolated in a horizontal direction.

When values for some sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations are required, such values may be interpolated by taking the average of a plurality of nearest neighbouring pixels.

At least one of step a) and step b) interpolating sub-pixel values directly using weighted sums may involve the calculation of an intermediate value for the sub-pixel values having a dynamic range greater than the specified dynamic range.

The intermediate value for a sub-pixel having $\frac{1}{2}^{N-1}$ sub-pixel resolution may be used the calculation of a sub-pixel value having $\frac{1}{2}^N$ sub-pixel resolution.

According to a second aspect of the invention, there is provided a method of interpolation in video coding in which an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, is interpolated to generate values for sub-pixels at fractional horizontal and vertical locations, the method comprising:

- a) when values for sub-pixels at half unit horizontal and unit vertical locations, and unit horizontal and half unit vertical locations are required, interpolating such values directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) when values for sub-pixels at half unit horizontal and half unit vertical locations are required, interpolating such values directly using a weighted sum of values for sub-pixels residing at half unit horizontal and unit vertical locations calculated according to step (a); and
- c) when values for sub-pixels at quarter unit horizontal and quarter unit vertical locations are required, interpolating such values by taking the average of at least one pair of a first pair of values of a sub-pixel located at a half unit horizontal and unit vertical location, and a sub-pixel located at a unit horizontal and half unit vertical location and a second pair of values of a pixel located at a unit horizontal and unit vertical location, and a sub-pixel located at a half unit horizontal and half unit vertical location.

According to a third aspect of the invention, there is provided a method of interpolation in video coding in which an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, is interpolated to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $\frac{1}{2}^x$ where x is a positive integer having a maximum value N, the method comprising:

- a) when values for sub-pixels at $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical locations are required, interpolating such values directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) when a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required, interpolating such a value directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

16

The sub-pixels used in the first weighted sum may be sub-pixels residing at $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical locations and the first weighted sum may be used to interpolate a value for a sub-pixel at $\frac{1}{2}^{N-1}$ unit horizontal and $\frac{1}{2}^N$ unit vertical location.

The sub-pixels used in the second weighted sum may be sub-pixels residing at unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical locations and the second weighted sum may be used to interpolate a value for a sub-pixel at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location.

When values for sub-pixels at $\frac{1}{2}^N$ unit horizontal and $\frac{1}{2}^N$ unit vertical locations are required, they may be interpolated by taking the average of at least one pair of a first pair of values of a sub-pixel located at a $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical location, and a sub-pixel located at a unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location and a second pair of values of a pixel located at a unit horizontal and unit vertical location, and a sub-pixel located at a $\frac{1}{2}^{N-1}$ unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical location.

In the foregoing, N may be equal an integer selected from a list consisting of the values 2, 3, and 4.

Sub-pixels at quarter unit horizontal location are to be interpreted as being sub-pixels having as their left-hand nearest neighbour a pixel at unit horizontal location and as their right-hand nearest neighbour a sub-pixel at half unit horizontal location as well as sub-pixels having as their left-hand nearest neighbour a sub-pixel at half unit horizontal location and as their right-hand nearest neighbour a pixel at unit horizontal location. Correspondingly, sub-pixels at quarter unit vertical location are to be interpreted as being sub-pixels having as their upper nearest neighbour a pixel at unit vertical location and as their lower nearest neighbour a sub-pixel at half unit vertical location as well as sub-pixels having as their upper nearest neighbour a sub-pixel at half unit vertical location and as their lower nearest neighbour a pixel at unit vertical location.

The term dynamic range, refers to the range of values which the sub-pixel values and the weighted sums can take.

Preferably changing the dynamic range, whether by extending it or reducing it, means changing the number of bits which are used to represent the dynamic range.

In an embodiment of the invention, the method is applied to an image that is sub-divided into a number of image blocks. Preferably each image block comprises four corners, each corner being defined by a pixel located at a unit horizontal and unit vertical location. Preferably the method is applied to each image block as the block becomes available for sub-pixel value interpolation. Alternatively, sub-pixel value interpolation according to the method of the invention is performed once all image blocks of an image have become available for sub-pixel value interpolation.

Preferably the method is used in video encoding. Preferably the method is used in video decoding.

In one embodiment of the invention, when used in encoding, the method is carried out as before-hand interpolation, in which values for all sub-pixels at half unit locations and values for all sub-pixels at quarter unit locations are calculated and stored before being subsequently used in the determination of a prediction frame during motion predictive coding. In alternative embodiments, the method is carried out as a combination of before-hand and on-demand interpolation. In this case, a certain proportion or category of sub-pixel values is calculated and stored before being used in the determination of a prediction frame and certain other sub-pixel values are calculated only when required during motion predictive coding.

17

Preferably, when the method is used in decoding, sub-pixels are only interpolated when their need is indicated by a motion vector.

According to a fourth aspect of the invention, there is provided a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the video coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $1/2^x$, where x is a positive integer having a maximum value N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical locations directly using a choice of a first weighted sum of values for sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and a second weighted sum of values for sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations, the first and second weighted sums of values being calculated according to step (a); and
- c) interpolate a value for a sub-pixel situated at a $1/2^N$ unit horizontal and $1/2^N$ unit vertical location by taking a weighted average of the value of a first sub-pixel or pixel situated at a $1/2^{N-m}$ unit horizontal and $1/2^{N-n}$ unit vertical location and the value of a second sub-pixel or pixel located at a $1/2^{N-p}$ unit horizontal and $1/2^{N-q}$ unit vertical location, variables m, n, p and q taking integer values in the range 1 to N such that the first and second sub-pixels or pixels are located diagonally with respect to the sub-pixel at $1/2^N$ unit horizontal and $1/2^N$ unit vertical location.

The video coder may comprise a video encoder. It may comprise a video decoder. There may be a codec comprising both the video encoder and the video decoder.

According to a fifth aspect of the invention, there is provided a communications terminal comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the video coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $1/2^x$, where x is a positive integer having a maximum value N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical locations directly using a choice of a first weighted sum of values for sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and a second weighted sum of values for sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations, the first and second weighted sums of values being calculated according to step (a); and
- c) interpolate a value for a sub-pixel situated at a $1/2^N$ unit horizontal and $1/2^N$ unit vertical location by taking a weighted average of the value of a first sub-pixel or pixel situated at a $1/2^{N-m}$ unit horizontal and $1/2^{N-n}$ unit vertical

18

location and the value of a second sub-pixel or pixel located at a $1/2^{N-p}$ unit horizontal and $1/2^{N-q}$ unit vertical location, variables m, n, p and q taking integer values in the range 1 to N such that the first and second sub-pixels or pixels are located diagonally with respect to the sub-pixel at $1/2^N$ unit horizontal and $1/2^N$ unit vertical location.

The communications terminal may comprise a video encoder. It may comprise a video decoder. Preferably, it comprises a video codec comprising a video encoder and a video decoder.

Preferably the communications terminal comprising a user interface, a processor and at least one of a transmitting block and a receiving block, and a video coder according to at least one of the third and fourth aspects of the invention. Preferably the processor controls the operation of the transmitting block and/or the receiving block and the video coder.

According to a sixth aspect of the invention, there is provided a telecommunications system comprising a communications terminal and a network, the telecommunications network and the communications terminal being connected by a communications link over which coded video can be transmitted, the communications terminal comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the video coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $1/2^x$, where x is a positive integer having a maximum value N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical locations directly using a choice of a first weighted sum of values for sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and a second weighted sum of values for sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations, the first and second weighted sums of values being calculated according to step (a); and
- c) interpolate a value for a sub-pixel situated at a $1/2^N$ unit horizontal and $1/2^N$ unit vertical location by taking a weighted average of the value of a first sub-pixel or pixel situated at a $1/2^{N-m}$ unit horizontal and $1/2^{N-n}$ unit vertical location and the value of a second sub-pixel or pixel located at a $1/2^{N-p}$ unit horizontal and $1/2^{N-q}$ unit vertical location, variables m, n, p and q taking integer values in the range 1 to N such that the first and second sub-pixels or pixels are located diagonally with respect to the sub-pixel at $1/2^N$ unit horizontal and $1/2^N$ unit vertical location.

Preferably the telecommunications system is a mobile telecommunications system comprising a mobile communications terminal and a wireless network, the connection between the mobile communications terminal and the wireless network being formed by a radio link. Preferably the network enables the communications terminal to communicate with other communications terminals connected to the network over communications links between the other communications terminals and the network.

According to a seventh aspect of the invention, there is provided a telecommunications system comprising a communications terminal and a network, the telecommunications network and the communications terminal being connected

by a communications link over which coded video can be transmitted, the network comprising a video coder for coding for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the video coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the fractional horizontal and vertical locations being defined according to $1/2^x$, where x is a positive integer having a maximum value N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical locations directly using a choice of a first weighted sum of values for sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and a second weighted sum of values for sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations, the first and second weighted sums of values being calculated according to step (a); and
- c) interpolate a value for a sub-pixel situated at a $1/2^N$ unit horizontal and $1/2^N$ unit vertical location by taking a weighted average of the value of a first sub-pixel or pixel situated at a $1/2^{N-m}$ unit horizontal and $1/2^{N-n}$ unit vertical location and the value of a second sub-pixel or pixel located at a $1/2^{N-p}$ unit horizontal and $1/2^{N-q}$ unit vertical location, variables m, n, p and q taking integer values in the range 1 to N such that the first and second sub-pixels or pixels are located diagonally with respect to the sub-pixel at $1/2^N$ unit horizontal and $1/2^N$ unit vertical location.

According to an eighth aspect of the invention there is provided a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the resolution of the sub-pixels being determined by a positive integer N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

The interpolator may be further adapted to form the first weighted sum using the values of sub-pixels residing at $1/2^{N-1}$ unit horizontal and unit vertical locations and to use the first weighted sum to interpolate a value for a sub-pixel at $1/2^{N-1}$ unit horizontal and $1/2^N$ unit vertical location.

The interpolator may be further adapted to form the second weighted sum using the values of sub-pixels residing at unit horizontal and $1/2^{N-1}$ unit vertical locations and to use the second weighted sum to interpolate a value for a sub-pixel at $1/2^N$ unit horizontal and $1/2^{N-1}$ unit vertical location.

The interpolator may be further adapted to interpolate values for sub-pixels at $1/2^N$ unit horizontal and $1/2^N$ unit vertical

locations by taking the average of at least one pair of a first pair of values of a sub-pixel located at a $1/2^{N-1}$ unit horizontal and unit vertical location, and a sub-pixel located at a unit horizontal and $1/2^{N-1}$ unit vertical location and a second pair of values of a pixel located at a unit horizontal and unit vertical location, and a sub-pixel located at a $1/2^{N-1}$ unit horizontal and $1/2^{N-1}$ unit vertical location.

According to a ninth aspect of the invention there is provided a communications terminal comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the resolution of the sub-pixels being determined by a positive integer N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

According to a tenth aspect of the invention there is provided a telecommunications system comprising a communications terminal and a network, the telecommunications network and the communications terminal being connected by a communications link over which coded video can be transmitted, the communications terminal comprising a video coder for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal and vertical locations, the resolution of the sub-pixels being determined by a positive integer N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $1/2^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $1/2^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

According to an eleventh aspect of the invention there is provided a telecommunications system comprising a communications terminal and a network, the telecommunications network and the communications terminal being connected by a communications link over which coded video can be transmitted, the network comprising a video coder for coding for coding an image comprising pixels arranged in rows and columns and represented by values having a specified dynamic range, the pixels in the rows residing at unit horizontal locations and the pixels in the columns residing at unit vertical locations, the coder comprising an interpolator adapted to generate values for sub-pixels at fractional horizontal

zontal and vertical locations, the resolution of the sub-pixels being determined by a positive integer N, the interpolator being adapted to:

- a) interpolate values for sub-pixels at $\frac{1}{2}^{N-1}$ unit horizontal and unit vertical locations, and unit horizontal and $\frac{1}{2}^{N-1}$ unit vertical locations directly using weighted sums of pixels residing at unit horizontal and unit vertical locations;
- b) interpolate a value for a sub-pixel at a sub-pixel horizontal and sub-pixel vertical location is required directly using a choice of a first weighted sum of values for sub-pixels located at a vertical location corresponding to that of the sub-pixel being calculated and a second weighted sum of values for sub-pixels located at a horizontal location corresponding to that of the sub-pixel being calculated.

According to the twelfth aspect of the invention, the disclosed embodiments are directed to a method for sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being arranged in rows and columns, the pixel and sub-pixel locations being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the method comprising:

- (a) interpolating a sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, according to a predetermined choice of a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $1/2$, $1/2$, and a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L, including zero, situated within a quadrant of the rectangular bounded region defined by corner pixels having co-ordinates $1/2$, $1/2$ and the nearest neighbouring pixel;
- (b) interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of both K and L, using weighted sums of the values of pixels located in rows and columns respectively; and
- (c) interpolating sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent bounded rectangular regions.

According to the thirteenth aspect of the invention, the disclosed embodiments are directed to a method for quarter resolution sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being arranged in rows and columns, the pixel and sub-pixel locations being

representable mathematically within the rectangular bounded region using the co-ordinate notation $K/4$, $L/4$, K and L being positive integers having respective values between zero and 4, the method comprising:

- (a) interpolating a sub-pixel value for a sub-pixel having co-ordinates with both K and L equal to 1 or 3, according to a predetermined choice of a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $2/4$, $2/4$, and a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with both K and L equal to zero, 2 or 4, situated within a quadrant of the rectangular bounded region defined by corner pixels having co-ordinates $2/4$, $2/4$ and the nearest neighbouring pixel;
- (b) interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to 2 and L equal zero and sub-pixels having co-ordinates with K equal to zero and L equal to 2, used in the interpolation of the sub-pixels having co-ordinates with both K and L equal to 1 or 3, using weighted sums of the values of pixels located in rows and columns respectively; and
- (c) interpolating a sub-pixel value for the sub-pixel having co-ordinates with both K and L equal to 2, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with both K and L equal to 1 or 3, using a predetermined choice of either a weighted sum of the values of the sub-pixel having co-ordinates with K equal to 2 and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the value of the sub-pixel having co-ordinates with K equal to zero and L equal to 2 and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

According to the fourteenth aspect of the invention, the disclosed embodiments are directed to a method for eighth resolution sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being arranged in rows and columns, the pixel and sub-pixel locations being representable mathematically with the rectangular bounded region using the co-ordinate notation $K/8$, $L/8$, K and L being positive integers having respective values between zero and 8, the method comprising:

- (a) interpolating a sub-pixel value for a sub-pixel having co-ordinates with both K and L equal to 1, 3, 5 or 7, according to a predetermined choice of a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $4/8$, $4/8$, and a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with both K and L equal to zero, 2, 4, 6 or 8, situated within a quadrant of the rectangular bounded region defined by corner pixels having co-ordinates $4/8$, $4/8$ and the nearest neighbouring pixel;
- (b) interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to 2, 4 or 6 and L equal zero and sub-pixels having co-ordinates with K equal to zero and L equal to 2, 4 or 6, used in the interpolation of the sub-pixels having co-ordinates with both K and L equal to 1, 3, 5 or 7, using weighted sums of the values of pixels located in rows and columns respectively; and
- (c) interpolating sub-pixel values for sub-pixels having co-ordinates with both K and L equal to 2, 4 or 6, used in the interpolation of sub-pixel values for the sub-pixels

23

having co-ordinates with both K and L equal to 1, 3, 5 or 7, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to 2, 4 or 6 and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to 2, 4 or 6 and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

According to the fifteenth aspect of the invention, the disclosed embodiments are directed to an apparatus for sub-pixel value interpolation, the apparatus being operable to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being arranged in rows and columns, the pixel and sub-pixel locations being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the apparatus comprising:

- (a) circuitry operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, according to a predetermined choice of a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates 1/2, 1/2, and a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L, including zero, situated within a quadrant of the rectangular bounded region defined by corner pixels having co-ordinates 1/2, 1/2 and the nearest neighbouring pixel;
- (b) circuitry operable to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of both K and L, using weighted sums of the values of pixels located in rows and columns respectively; and
- (c) circuitry operable to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent bounded rectangular regions.

In one embodiment the method includes comprising using a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, wherein when the chosen weighted average is that involving the value of a nearest neighbouring pixel and the value of the sub-pixel situated at co-ordinates 1/2, 1/2, selecting the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the nearest-neighbouring pixel and the sub-pixel situated at co-

24

ordinates 1/2, 1/2 to the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

In one embodiment the method includes comprising using a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, wherein when the chosen weighted average is that involving the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L, selecting the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the sub-pixels having co-ordinates with even values of both K and L to the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

In one embodiment the method includes comprising using first and second weights with equal values when the nearest-neighbouring pixel and sub-pixel situated at co-ordinates 1/2, 1/2 are equidistant from the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

In one embodiment the method includes comprising using first and second weights with equal values when the sub-pixels having co-ordinates with even values of both K and L are equidistant from the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

In one embodiment the method includes interpolating sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an even value and L equal to an odd value is also required.

In one embodiment the method includes comprising interpolating sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an odd value and L equal to an even value is also required.

In one embodiment the method includes comprising interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to an odd value O and L equal to an even value E, not including zero or 2^N , by taking an average of the value of a first sub-pixel having co-ordinates with K equal to the even value O-1 and L equal to E and a second sub-pixel having co-ordinates with K equal to the even value O+1 and L equal to E.

In one embodiment the method includes comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2 and L equal to zero.

In one embodiment the method includes comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to zero.

25

In one embodiment the method includes comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2 and L equal to 2^N .

In one embodiment the method includes comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to 2^N .

In one embodiment the method includes comprising interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to an even value E, not including zero or 2^N , and L equal to an odd value O, by taking an average of the value of a first sub-pixel having co-ordinates with K equal to E and L equal to the even value O-1 and a second sub-pixel having co-ordinates with K equal to E and L equal to the even value O+1.

In one embodiment the method includes comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to zero and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

In one embodiment the method includes comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

In one embodiment the method includes comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 0 and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to zero and L equal to 2^N-2 .

In one embodiment the method includes comprising interpolating a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-2 .

In one embodiment the method includes comprising interpolating a sub-pixel value for the sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N-1 , by taking a weighted average of the values of the four corner pixels that define the rectangular bounded region.

In one embodiment the method includes comprising selecting a value for N from a list consisting of the values 2, 3, and 4.

In one embodiment the apparatus is operable to use a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, wherein when the chosen weighted average is that involving the value of a nearest neighbouring pixel and the value of the sub-pixel situated at co-ordinates 1/2, 1/2, the apparatus is operable to select the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the nearest-neighbouring pixel and the sub-pixel situated at co-ordinates 1/2, 1/2 to the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

In one embodiment the apparatus is operable to use a first and a second weight in the weighted average chosen to inter-

26

polate the sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, wherein when the chosen weighted average is that involving the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L, the apparatus is operable to select the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the sub-pixels having co-ordinates with even values of both K and L to the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

In one embodiment the apparatus is operable to use first and second weights with equal values when the nearest-neighbouring pixel and sub-pixel situated at co-ordinates 1/2, 1/2 are equidistant from the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

In one embodiment the apparatus is operable to use first and second weights with equal values when the sub-pixels having co-ordinates with even values of both K and L are equidistant from the sub-pixel having co-ordinates with odd values of both K and L whose value is being interpolated.

In one embodiment the apparatus is operable to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an even value and L equal to an odd value is also required.

In one embodiment the apparatus is operable to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of both K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of both K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an odd value and L equal to an even value is also required.

In one embodiment the apparatus is operable to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an odd value O and L equal to an even value E, not including zero or 2^N , by taking an average of the value of a first sub-pixel having co-ordinates with K equal to the even value O-1 and L equal to E and a second sub-pixel having co-ordinates with K equal to the even value O+1 and L equal to E.

In one embodiment the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2 and L equal to zero.

In one embodiment the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to zero.

In one embodiment the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to 2^N , by taking an average of the value

27

of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2 and L equal to 2^N .

In one embodiment the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to 2^N .

In one embodiment the apparatus is operable to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value E, not including zero or 2^N , and L equal to an odd value O, by taking an average of the value of a first sub-pixel having co-ordinates with K equal to E and L equal to the even value O-1 and a second sub-pixel having co-ordinates with K equal to E and L equal to the even value O+1.

In one embodiment the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to zero and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

In one embodiment the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

In one embodiment the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 0 and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to zero and L equal to 2^N-2 .

In one embodiment the apparatus is operable to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-2 .

In one embodiment the apparatus is operable to interpolate a sub-pixel value for the sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N-1 , by taking a weighted average of the values of the four corner pixels that define the rectangular bounded region.

In one embodiment the apparatus includes N is set equal to 2.

In one embodiment the apparatus includes N is set equal to 3.

In one embodiment the apparatus includes a video encoder comprising an apparatus for sub-pixel value interpolation.

In one embodiment the apparatus includes a still image encoder comprising an apparatus for sub-pixel value interpolation.

In one embodiment the apparatus includes a video decoder comprising an apparatus for sub-pixel value interpolation.

In one embodiment the apparatus includes a still image decoder comprising an apparatus for sub-pixel value interpolation.

In one embodiment the apparatus includes a codec comprising a video encoder and a video decoder.

In one embodiment the apparatus includes a codec comprising a still image encoder and a still image decoder.

In one embodiment the apparatus includes a communications terminal comprising a video encoder.

In one embodiment the apparatus includes a communications terminal comprising a still image encoder.

28

In one embodiment the apparatus includes a communications terminal comprising a video decoder.

In one embodiment the apparatus includes a communications terminal comprising a still image decoder.

BRIEF DESCRIPTION OF THE FIGURES

An embodiment of the invention will now be described by way of example only with reference to the accompanying drawings in which:

FIG. 1 shows a video encoder according to the prior art;

FIG. 2 shows a video decoder according to the prior art;

FIG. 3 shows the types of frames used in video encoding;

FIGS. 4a, 4b, and 4c show steps in block-matching;

FIG. 5 illustrates the process of motion estimation to sub-pixel resolution;

FIG. 6 shows a terminal device comprising video encoding and decoding equipment in which the method of the invention may be implemented;

FIG. 7 shows a video encoder according an embodiment of the present invention;

FIG. 8 shows a video decoder according to an embodiment of the present invention;

FIGS. 9 and 10 have not been used and any such figures should be disregarded;

FIG. 11 shows a schematic diagram of a mobile telecommunications network according to an embodiment of the present invention;

FIG. 12a shows a notation for describing pixel and sub-pixel locations specific to TML5;

FIG. 12b shows interpolation of a half resolution sub-pixels;

FIG. 12c shows interpolation of a half resolution sub-pixels;

FIG. 13a shows a notation for describing pixel and sub-pixel locations specific to TML6;

FIG. 13b shows interpolation of a half resolution sub-pixels;

FIG. 13c shows interpolation of a half resolution sub-pixels;

FIG. 14a shows a notation for describing pixel and sub-pixel locations specific to the invention;

FIG. 14b shows interpolation of a half resolution sub-pixels according to the invention;

FIG. 14c shows interpolation of a half resolution sub-pixels according to the invention;

FIG. 15 shows possible choices of diagonal interpolation for sub-pixels;

FIG. 16 shows the half resolution sub-pixel values required to calculate other half resolution sub-pixel values;

FIG. 17a shows the half resolution sub-pixel values that must be calculated in order to interpolate values for quarter resolution sub-pixels in an image block using the interpolation method of TML5;

FIG. 17b shows the half resolution sub-pixel values that must be calculated in order to interpolate values for quarter resolution sub-pixels in an image block using the interpolation method according to the invention;

FIG. 18a shows the numbers of half resolution sub-pixels that must be calculated in order to obtain values for quarter resolution sub-pixels within an image block using the sub-pixel value interpolation method according to TML5;

FIG. 18b shows the numbers of half resolution sub-pixels that must be calculated in order to obtain values for quarter resolution sub-pixels within an image block using the sub-pixel value interpolation method according to the invention;

FIG. 19 shows a numbering scheme for each of the 15 sub-pixel positions;

FIG. 20 shows nomenclature used to describe pixels, half resolution sub-pixels, quarter resolution sub-pixels and eighth resolution sub-pixels

FIG. 21a shows the diagonal direction to be used in the interpolation of each eighth resolution sub-pixel in an embodiment of the invention;

FIG. 21b shows the diagonal direction to be used in the interpolation of each eighth resolution sub-pixel in another embodiment of the invention; and

FIG. 22 shows nomenclature used to describe eighth resolution sub-pixels within an image.

DETAILED DESCRIPTION

FIGS. 1 to 5, 12a, 12b, 12c, 13a, 13b, and 13c have been described in the foregoing.

FIG. 6 presents a terminal device comprising video encoding and decoding equipment which may be adapted to operate in accordance with the present invention. More precisely, the figure illustrates a multimedia terminal 60 implemented according to ITU-T recommendation H.324. The terminal can be regarded as a multimedia transceiver device. It includes elements that capture, encode and multiplex multimedia data streams for transmission via a communications network, as well as elements that receive, de-multiplex, decode and display received multimedia content. ITU-T recommendation H.324 defines the overall operation of the terminal and refers to other recommendations that govern the operation of its various constituent parts. This kind of multimedia terminal can be used in real-time applications such as conversational videotelephony, or non real-time applications such as the retrieval/streaming of video clips, for example from a multimedia content server in the Internet.

In the context of the present invention, it should be appreciated that the H.324 terminal shown in FIG. 6 is only one of a number of alternative multimedia terminal implementations suited to application of the inventive method. It should also be noted that a number of alternatives exist relating to the location and implementation of the terminal equipment. As illustrated in FIG. 6, the multimedia terminal may be located in communications equipment connected to a fixed line telephone network such as an analogue PSTN (Public Switched Telephone Network). In this case the multimedia terminal is equipped with a modem 71, compliant with ITU-T recommendations V.8, V.34 and optionally V.8bis. Alternatively, the multimedia terminal may be connected to an external modem. The modem enables conversion of the multiplexed digital data and control signals produced by the multimedia terminal into an analogue form suitable for transmission over the PSTN. It further enables the multimedia terminal to receive data and control signals in analogue form from the PSTN and to convert them into a digital data stream that can be demultiplexed and processed in an appropriate manner by the terminal.

An H.324 multimedia terminal may also be implemented in such a way that it can be connected directly to a digital fixed line network, such as an ISDN (Integrated Services Digital Network). In this case the modem 71 is replaced with an ISDN user-network interface. In FIG. 6, this ISDN user-network interface is represented by alternative block 72.

H.324 multimedia terminals may also be adapted for use in mobile communication applications. If used with a wireless communication link, the modem 71 can be replaced with any appropriate wireless interface, as represented by alternative block 73 in FIG. 6. For example, an H.324/M multimedia

terminal can include a radio transceiver enabling connection to the current 2nd generation GSM mobile telephone network, or the proposed 3rd generation UMTS (Universal Mobile Telephone System).

It should be noted that in multimedia terminals designed for two-way communication, that is for transmission and reception of video data, it is advantageous to provide both a video encoder and video decoder implemented according to the present invention. Such an encoder and decoder pair is often implemented as a single combined functional unit, referred to as a 'codec'.

Because a video encoder according to the invention performs motion compensated video encoding to sub-pixel resolution using a specific interpolation scheme and a particular combination of before-hand and on-demand sub-pixel value interpolation, it is generally necessary for a video decoder of a receiving terminal to be implemented in a manner compatible with the encoder of the transmitting terminal which formed the compressed video data stream. Failure to ensure the motion compensation and the accuracy of reconstructed video frames.

A typical H.324 multimedia terminal will now be described in further detail with reference to FIG. 6.

The multimedia terminal 60 includes a variety of elements referred to as 'terminal equipment'. This includes video, audio and telematic devices, denoted generically by reference numbers 61, 62 and 63, respectively. The video equipment 61 may include, for example, a video camera for capturing video images, a monitor for displaying received video content and optional video processing equipment. The audio equipment 62 typically includes a microphone, for example for capturing spoken messages, and a loudspeaker for reproducing received audio content. The audio equipment may also include additional audio processing units. The telematic equipment 63, may include a data terminal, keyboard, electronic whiteboard or a still image transceiver, such as a fax unit.

The video equipment 61 is coupled to a video codec 65. The video codec 65 comprises a video encoder and a corresponding video decoder both implemented according to the invention. Such an encoder and a decoder will be described in the following. The video codec 65 is responsible for encoding captured video data in an appropriate form for further transmission over a communications link and decoding compressed video content received from the communications network. In the example illustrated in FIG. 6, the video codec is implemented according to ITU-T recommendation H.263, with appropriate modifications to implement the sub-pixel value interpolation method according to the invention in both the encoder and the decoder of the video codec.

Similarly, the terminal's audio equipment is coupled to an audio codec, denoted in FIG. 6 by reference number 66. Like the video codec, the audio codec comprises an encoder/decoder pair. It converts audio data captured by the terminal's audio equipment into a form suitable for transmission over the communications link and transforms encoded audio data received from the network back into a form suitable for reproduction, for example on the terminal's loudspeaker. The output of the audio codec is passed to a delay block 67. This compensates for the delays introduced by the video coding process and thus ensures synchronisation of audio and video content.

The system control block 64 of the multimedia terminal controls end-to-network signalling using an appropriate control protocol (signalling block 68) to establish a common mode of operation between a transmitting and a receiving terminal. The signalling block 68 exchanges information

31

about the encoding and decoding capabilities of the transmitting and receiving terminals and can be used to enable the various coding modes of the video encoder. The system control block **64** also controls the use of data encryption. Information regarding the type of encryption to be used in data transmission is passed from encryption block **69** to the multiplexer/de-multiplexer (MUX/DMUX unit) **70**.

During data transmission from the multimedia terminal, the MUX/DMUX unit **70** combines encoded and synchronised video and audio streams with data input from the telematic equipment **63** and possible control data, to form a single bit-stream. Information concerning the type of data encryption (if any) to be applied to the bit-stream, provided by encryption block **69**, is used to select an encryption mode. Correspondingly, when a multiplexed and possibly encrypted multimedia bit-stream is being received, MUX/DMUX unit **70** is responsible for decrypting the bit-stream, dividing it into its constituent multimedia components and passing those components to the appropriate codec(s) and/or terminal equipment for decoding and reproduction.

It should be noted that the functional elements of the multimedia terminal, video encoder, decoder and video codec according to the invention can be implemented as software or dedicated hardware, or a combination of the two. The video encoding and decoding methods according to the invention are particularly suited for implementation in the form of a computer program comprising machine-readable instructions for performing the functional steps of the invention. As such, the encoder and decoder according to the invention may be implemented as software code stored on a storage medium and executed in a computer, such as a personal desktop computer, in order to provide that computer with video encoding and/or decoding functionality.

If the multimedia terminal **60** is a mobile terminal, that is if it is equipped with a radio transceiver **73**, it will be understood by those skilled in the art that it may also comprise additional elements. In one embodiment it comprises a user interface having a display and a keyboard, which enables operation of the multimedia terminal **60** by a user, together with necessary functional blocks including a central processing unit, such as a microprocessor, which controls the blocks responsible for different functions of the multimedia terminal, a random access memory RAM, a read only memory ROM, and a digital camera. The microprocessor's operating instructions, that is program code corresponding to the basic functions of the multimedia terminal **60**, is stored in the read-only memory ROM and can be executed as required by the microprocessor, for example under control of the user. In accordance with the program code, the microprocessor uses the radio transceiver **73** to form a connection with a mobile communication network, enabling the multimedia terminal **60** to transmit information to and receive information from the mobile communication network over a radio path.

The microprocessor monitors the state of the user interface and controls the digital camera. In response to a user command, the microprocessor instructs the camera to record digital images into the RAM. Once an image is captured, or alternatively during the capturing process, the microprocessor segments the image into image segments (for example macroblocks) and uses the encoder to perform motion compensated encoding for the segments in order to generate a compressed image sequence as explained in the foregoing description. A user may command the multimedia terminal **60** to display the captured images on its display or to send the compressed image sequence using the radio transceiver **73** to another multimedia terminal, a video telephone connected to a fixed line network (PSTN) or some other telecommunica-

32

tions device. In a preferred embodiment, transmission of image data is started as soon as the first segment is encoded so that the recipient can start a corresponding decoding process with a minimum delay.

FIG. **11** is a schematic diagram of a mobile telecommunications network according to an embodiment of the invention. Multimedia terminals MS are in communication with base stations BTS by means of a radio link. The base stations BTS are further connected, through a so-called Abis interface, to a base station controller BSC, which controls and manages several base stations.

The entity formed by a number of base stations BTS (typically, by a few tens of base stations) and a single base station controller BSC, controlling the base stations, is called a base station subsystem BSS. Particularly, the base station controller BSC manages radio communication channels and handovers. The base station controller BSC is also connected, through a so-called A interface, to a mobile services switching centre MSC, which co-ordinates the formation of connections to and from mobile stations. A further connection is made, through the mobile service switching centre MSC, to outside the mobile communications network. Outside the mobile communications network there may further reside other network(s) connected to the mobile communications network by gateway(s) GTW, for example the Internet or a Public Switched Telephone Network (PSTN). In such an external network, or within the telecommunications network, there may be located video decoding or encoding stations, such as computers PC. In an embodiment of the invention, the mobile telecommunications network comprises a video server VSRVR to provide video data to a MS subscribing to such a service. The video data is compressed using the motion compensated video compression method as described in the foregoing. The video server may function as a gateway to an online video source or it may comprise previously recorded video clips. Typical videotelephony applications may involve, for example, two mobile stations or one mobile station MS and a videotelephone connected to the PSTN, a PC connected to the Internet or a H.261 compatible terminal connected either to the Internet or to the PSTN.

FIG. **7** shows a video encoder **700** according to an embodiment the invention. FIG. **8** shows a video decoder **800** according to an embodiment the invention.

The encoder **700** comprises an input **701** for receiving a video signal from a camera or other video source (not shown). It further comprises a DCT transformer **705**, a quantiser **706**, an inverse quantiser **709**, an inverse DCT transformer **710**, combiners **712** and **716**, a before-hand sub-pixel interpolation block **730**, a frame store **740** and an on-demand sub-pixel interpolation block **750**, implemented in combination with motion estimation block **760**. The encoder also comprises a motion field coding block **770** and a motion compensated prediction block **780**. Switches **702** and **714** are operated co-operatively by a control manager **720** to switch the encoder between an INTRA-mode of video encoding and an INTER-mode of video encoding. The encoder **700** also comprises a multiplexer unit (MUX/DMUX) **790** to form a single bit-stream from the various types of information produced by the encoder **700** for further transmission to a remote receiving terminal, or for example for storage on a mass storage medium such as a computer hard drive (not shown).

It should be noted that the presence and implementations of before-hand sub-pixel interpolation block **730** and on-demand sub-pixel value interpolation block **750** in the encoder architecture depend on the way in which the sub-pixel interpolation method according to the invention is applied. In embodiments of the invention in which before-hand sub-pixel

33

value interpolation is not performed, encoder 700 does not comprise before-hand sub-pixel value interpolation block 730. In other embodiments of the invention, only before-hand sub-pixel interpolation is performed and thus the encoder does not include on-demand sub-pixel value interpolation block 750. In embodiments in which both before-hand and on-demand sub-pixel value interpolation are performed, both blocks 730 and 750 are present in the encoder 700.

Operation of the encoder 700 according to the invention will now be described in detail. In the description, it will be assumed that each frame of uncompressed video, received from the video source at the input 701, is received and processed on a macroblock-by-macroblock basis, preferably in raster-scan order. It will further be assumed that when the encoding of a new video sequence starts, the first frame of the sequence is encoded in INTRA-mode. Subsequently, the encoder is programmed to code each frame in INTER-format, unless one of the following conditions is met: 1) it is judged that the current frame being coded is so dissimilar from the reference frame used in its prediction that excessive prediction error information is produced; 2) a predefined INTRA frame repetition interval has expired; or 3) feedback is received from a receiving terminal indicating a request for a frame to be coded in INTRA format.

The occurrence of condition 1) is detected by monitoring the output of the combiner 716. The combiner 716 forms a difference between the current macroblock of the frame being coded and its prediction, produced in the motion compensated prediction block 780. If a measure of this difference (for example a sum of absolute differences of pixel values) exceeds a predetermined threshold, the combiner 716 informs the control manager 720 via a control line 717 and the control manager 720 operates the switches 702 and 714 so as to switch the encoder 700 into INTRA coding mode. Occurrence of condition 2) is monitored by means of a timer or frame counter implemented in the control manager 720, in such a way that if the timer expires, or the frame counter reaches a predetermined number of frames, the control manager 720 operates the switches 702 and 714 to switch the encoder into INTRA coding mode. Condition 3) is triggered if the control manager 720 receives a feedback signal from, for example, a receiving terminal, via control line 718 indicating that an INTRA frame refresh is required by the receiving terminal. Such a condition might arise, for example, if a previously transmitted frame were badly corrupted by interference during its transmission, rendering it impossible to decode at the receiver. In this situation, the receiver would issue a request for the next frame to be encoded in INTRA format, thus re-initializing the coding sequence.

It will further be assumed that the encoder and decoder are implemented in such a way as to allow the determination of motion vectors with a spatial resolution of up to quarter-pixel resolution. As will be seen in the following, finer levels of resolution are also possible.

Operation of the encoder 700 in INTRA coding mode will now be described. In INTRA-mode, the control manager 720 operates the switch 702 to accept video input from input line 719. The video signal input is received macroblock by macroblock from input 701 via the input line 719 and each macroblock of original image pixels is transformed into DCT coefficients by the DCT transformer 705. The DCT coefficients are then passed to the quantiser 706, where they are quantised using a quantisation parameter QP. Selection of the quantisation parameter QP is controlled by the control manager 720 via control line 722. Each DCT transformed and quantised macroblock that makes up the INTRA coded image information 723 of the frame is passed from the quantiser 706

34

to the MUX/DMUX 790. The MUX/DMUX 790 combines the INTRA coded image information with possible control information (for example header data, quantisation parameter information, error correction data etc.) to form a single bit-stream of coded image information 725. Variable length coding (VLC) is used to reduce redundancy of the compressed video bit-stream, as is known to those skilled in the art.

A locally decoded picture is formed in the encoder 700 by passing the data output by the quantiser 706 through inverse quantiser 709 and applying an inverse DCT transform 710 to the inverse-quantised data. The resulting data is then input to the combiner 712. In INTRA mode, switch 714 is set so that the input to the combiner 712 via the switch 714 is set to zero. In this way, the operation performed by the combiner 712 is equivalent to passing the decoded image data formed by the inverse quantiser 709 and the inverse DCT transform 710 unaltered.

In embodiments of the invention in which before-hand sub-pixel value interpolation is performed, the output from combiner 712 is applied to before-hand sub-pixel interpolation block 730. The input to the before-hand sub-pixel value interpolation block 730 takes the form of decoded image blocks. In the before-hand sub-pixel value interpolation block 730, each decoded macroblock is subjected to sub-pixel interpolation in such a way that a predetermined sub-set of sub-pixel resolution sub-pixel values is calculated according to the interpolation method of the invention and is stored together with the decoded pixel values in frame store 740.

In embodiments in which before-hand sub-pixel interpolation is not performed, before-hand sub-pixel interpolation block is not present in the encoder architecture and the output from combiner 712, comprising decoded image blocks, is applied directly to frame store 740.

As subsequent macroblocks of the current frame are received and undergo the previously described coding and decoding steps in blocks 705, 706, 709, 710, 712, a decoded version of the INTRA frame is built up in the frame store 740. When the last macroblock of the current frame has been INTRA coded and subsequently decoded, the frame store 740 contains a completely decoded frame, available for use as a prediction reference frame in coding a subsequently received video frame in INTER format. In embodiments of the invention in which before-hand sub-pixel value interpolation is performed, the reference frame held in frame store 740 is at least partially interpolated to sub-pixel resolution.

Operation of the encoder 700 in INTER coding mode will now be described. In INTER coding mode, the control manager 720 operates switch 702 to receive its input from line 721, which comprises the output of the combiner 716. The combiner 716 forms prediction error information representing the difference between the current macroblock of the frame being coded and its prediction, produced in the motion compensated prediction block 780. The prediction error information is DCT transformed in block 705 and quantised in block 706 to form a macroblock of DCT transformed and quantised prediction error information. Each macroblock of DCT transformed and quantised prediction error information is passed from the quantiser 706 to the MUX/DMUX unit 790. The MUX/DMUX unit 790 combines the prediction error information 723 with motion coefficients 724 (described in the following) and control information (for example header data, quantisation parameter information, error correction data etc.) to form a single bit-stream of coded image information, 725.

Locally decoded prediction error information for the each macroblock of the INTER coded frame is then formed in the encoder 700 by passing the encoded prediction error infor-

35

mation 723 output by the quantiser 706 through the inverse quantiser 709 and applying an inverse DCT transform in block 710. The resulting locally decoded macroblock of prediction error information is then input to combiner 712. In INTER-mode, switch 714 is set so that the combiner 712 also receives motion predicted macroblocks for the current INTER frame, produced in the motion compensated prediction block 780. The combiner 712 combines these two pieces of information to produce reconstructed image blocks for the current INTER frame.

As described above when considering INTRA coded frames, in embodiments of the invention in which before-hand sub-pixel value interpolation is performed, the output from combiner 712 is applied to the before-hand sub-pixel interpolation block 730. Thus, the input to the before-hand sub-pixel value interpolation block 730 in INTER coding mode also takes the form of decoded image blocks. In the before-hand sub-pixel value interpolation block 730, each decoded macroblock is subjected to sub-pixel interpolation in such a way that a predetermined sub-set of sub-pixel values is calculated according to the interpolation method of the invention and is stored together with the decoded pixel values in frame store 740. In embodiments in which before-hand sub-pixel interpolation is not performed, before-hand sub-pixel interpolation block is not present in the encoder architecture and the output from combiner 712, comprising decoded image blocks, is applied directly to frame store 740.

As subsequent macroblocks of the video signal are received from the video source and undergo the previously described coding and decoding steps in blocks 705, 706, 709, 710, 712, a decoded version of the INTER frame is built up in the frame store 740. When the last macroblock of the frame has been INTER coded and subsequently decoded, the frame store 740 contains a completely decoded frame, available for use as a prediction reference frame in encoding a subsequently received video frame in INTER format. In embodiments of the invention in which before-hand sub-pixel value interpolation is performed, the reference frame held in frame store 740 is at least partially interpolated to sub-pixel resolution.

Formation of a prediction for a macroblock of the current frame will now be described.

Any frame encoded in INTER format requires a reference frame for motion compensated prediction. This means, inter alia, that when encoding a video sequence, the first frame to be encoded, whether it is the first frame in the sequence, or some other frame, must be encoded in INTRA format. This, in turn, means that when the video encoder 700 is switched into INTER coding mode by control manager 720, a complete reference frame, formed by locally decoding a previously encoded frame, is already available in the frame store 740 of the encoder. In general, the reference frame is formed by locally decoding either an INTRA coded frame or an INTER coded frame.

The first step in forming a prediction for a macroblock of the current frame is performed by motion estimation block 760. The motion estimation block 760 receives the current macroblock of the frame being coded via line 727 and performs a block matching operation in order to identify a region in the reference frame which corresponds substantially with the current macroblock. According to the invention, the block-matching process is performed to sub-pixel resolution in a manner that depends on the implementation of the encoder 700 and the degree of before-hand sub-pixel interpolation performed. However, the basic principle behind the block-matching process is similar in all cases. Specifically, motion estimation block 760 performs block-matching by

36

calculating difference values (e.g. sums of absolute differences) representing the difference in pixel values between the macroblock of the current frame under examination and candidate best-matching regions of pixels/sub-pixels in the reference frame. A difference value is produced for all possible offsets (e.g. quarter- or one eighth sub-pixel precision x, y displacements) between the macroblock of the current frame and candidate test region within a predefined search region of the reference frame and motion estimation block 760 determines the smallest calculated difference value. The offset between the macroblock in the current frame and the candidate test region of pixel values/sub-pixel values in the reference frame that yields the smallest difference value defines the motion vector for the macroblock in question. In certain embodiments of the invention, an initial estimate for the motion vector having unit pixel precision is first determined and then refined to a finer level of sub-pixel precision, as described in the foregoing.

In embodiments of the encoder in which before-hand sub-pixel value interpolation is not performed, all sub-pixel values required in the block matching process are calculated in on-demand sub-pixel value interpolation block 750. Motion estimation block 760 controls on-demand sub-pixel value interpolation block 750 to calculate each sub-pixel value needed in the block-matching process in an on-demand fashion, as and when it is required. In this case, motion estimation block 760 may be implemented so as to perform block-matching as a one-step process, in which case a motion vector with the desired sub-pixel resolution is sought directly, or it may be implemented so as to perform block-matching as a two step process. If the two-step process is adopted, the first step may comprise a search for e.g. a full or half-pixel resolution motion vector and the second step is performed in order to refine the motion vector to the desired sub-pixel resolution. As block matching is an exhaustive process, in which blocks of $n \times m$ pixels in the current frame are compared one-by-one with blocks of $n \times m$ pixels or sub-pixels in the interpolated reference frame, it should be appreciated that a sub-pixel calculated in an on-demand fashion by the on-demand pixel interpolation block 750 may need to be calculated multiple times as successive difference values are determined. In a video encoder, this approach is not the most efficient possible in terms of computational complexity/burden.

In embodiments of the encoder which use only before-hand sub-pixel value interpolation, block-matching may be performed as a one step process, as all sub-pixel values of the reference frame required to determine a motion vector with the desired sub-pixel resolution are calculated before-hand in block 730 and stored in frame store 740. Thus, they are directly available for use in the block-matching process and can be retrieved as required from frame store 740 by motion estimation block 760. However, even in the case where all sub-pixel values are available from frame store 740, it is still more computationally efficient to perform block-matching as a two-step process, as fewer difference calculations are required. It should be appreciated that while full before-hand sub-pixel value interpolation reduces computational complexity in the encoder, it is not the most efficient approach in terms of memory consumption.

In embodiments of the encoder in which both before-hand and on-demand sub-pixel value interpolation are used, motion estimation block 760 is implemented in such a way that it can retrieve sub-pixel values previously calculated in before-hand sub-pixel value interpolation block 730 and stored in frame store 740 and further control on-demand sub-pixel value interpolation block 750 to calculate any additional sub-pixel values that may be required. The block-

matching process may be performed as a one-step or a two-step process. If a two-step implementation is used, before-hand calculated sub-pixel values retrieved from frame store 740 may be used in the first step of the process and the second step may be implemented so as to use sub-pixel values calculated by on-demand sub-pixel value interpolation block 750. In this case, certain sub-pixel values used in the second step of the block matching process may need to be calculated multiple times as successive comparisons are made, but the number of such duplicate calculations is significantly less than if before-hand sub-pixel value calculation is not used. Furthermore, memory consumption is reduced with respect to embodiments in which only before-hand sub-pixel value interpolation is used.

Once the motion estimation block 760 has produced a motion vector for the macroblock of the current frame under examination, it outputs the motion vector to the motion field coding block 770. Motion field coding block 770 then approximates the motion vector received from motion estimation block 760 using a motion model. The motion model generally comprises a set of basis functions. More specifically, the motion field coding block 770 represents the motion vector as a set of coefficient values (known as motion coefficients) which, when multiplied by the basis functions, form an approximation of the motion vector. The motion coefficients 724 are passed from motion field coding block 770 to motion compensated prediction block 780. Motion compensated prediction block 780 also receives the pixel/sub-pixel values of the best-matching candidate test region of the reference frame identified by motion estimation block 760. In FIG. 7, these values are shown to be passed via line 729 from on-demand sub-pixel interpolation block 750. In alternative embodiments of the invention, the pixel values in question are provided from the motion estimation block 760 itself.

Using the approximate representation of the motion vector generated by motion field coding block 770 and the pixel/sub-pixel values of the best-matching candidate test region, motion compensated prediction block 780 produces a macroblock of predicted pixel values. The macroblock of predicted pixel values represents a prediction for the pixel values of the current macroblock generated from the interpolated reference frame. The macroblock of predicted pixel values is passed to the combiner 716 where it is subtracted from the new current frame in order to produce prediction error information 723 for the macroblock, as described in the foregoing.

The motion coefficients 724 formed by motion field coding block are also passed to the MUX/DMUX unit 790, where they are combined with prediction error information 723 for the macroblock in question and possible control information from control manager 720 to form an encoded video stream 725 for transmission to a receiving terminal.

Operation of a video decoder 800 according to the invention will now be described. Referring to FIG. 8, the decoder 800 comprises a demultiplexing unit (MUX/DMUX) 810, which receives the encoded video stream 725 from the encoder 700 and demultiplexes it, an inverse quantiser 820, an inverse DCT transformer 830, a motion compensated prediction block 840, a frame store 850, a combiner 860, a control manager 870, an output 880, before-hand sub-pixel value interpolation block 845 and on-demand sub-pixel interpolation block 890 associated with the motion compensated prediction block 840. In practice the control manager 870 of the decoder 800 and the control manager 720 of the encoder 700 may be the same processor. This may be the case if the encoder 700 and decoder 800 are part of the same video codec.

FIG. 8 shows an embodiment in which a combination of before-hand and on-demand sub-pixel value interpolation is used in the decoder. In other embodiments, only before-hand sub-pixel value interpolation is used, in which case decoder 800 does not include on-demand sub-pixel value interpolation block 890. In a preferred embodiment of the invention, no before-hand sub-pixel value interpolation is used in the decoder and therefore before-hand sub-pixel value interpolation block 845 is omitted from the decoder architecture. If both before-hand and on-demand sub-pixel value interpolation are performed, the decoder comprises both blocks 845 and 890.

The control manager 870 controls the operation of the decoder 800 in response to whether an INTRA or an INTER frame is being decoded. An INTRA/INTER trigger control signal, which causes the decoder to switch between decoding modes is derived, for example, from picture type information provided in the header portion of each compressed video frame received from the encoder. The INTRA/INTER trigger control signal is passed to control manager 870 via control line 815, together with other video codec control signals demultiplexed from the encoded video stream 725 by the MUX/DMUX unit 810.

When an INTRA frame is decoded, the encoded video stream 725 is demultiplexed into INTRA coded macroblocks and control information. No motion vectors are included in the encoded video stream 725 for an INTRA coded frame. The decoding process is performed macroblock-by-macroblock. When the encoded information 723 for a macroblock is extracted from video stream 725 by MUX/DMUX unit 810, it is passed to inverse quantiser 820. The control manager controls inverse quantiser 820 to apply a suitable level of inverse quantisation to the macroblock of encoded information, according to control information provided in video stream 725. The inverse quantised macroblock is then inversely transformed in the inverse DCT transformer 830 to form a decoded block of image information. Control manager 870 controls combiner 860 to prevent any reference information being used in the decoding of the INTRA coded macroblock. The decoded block of image information is passed to the video output 880 of the decoder.

In embodiments of the decoder which employ before-hand sub-pixel value interpolation, the decoded block of image information (i.e. pixel values) produced as a result of the inverse quantisation and inverse transform operations performed in blocks 820 and 830 is passed to before-hand sub-pixel value interpolation block 845. Here, sub-pixel value interpolation is performed according to the method of the invention, the degree of before-hand sub-pixel value interpolation applied being determined by the details of the decoder implementation. In embodiments of the invention in which on-demand sub-pixel value interpolation is not performed, before-hand sub-pixel value interpolation block 845 interpolates all sub-pixel values. In embodiments that use a combination of before-hand and on-demand sub-pixel value interpolation, before-hand sub-pixel value interpolation block 845 interpolates a certain sub-set of sub-pixel values. This may comprise, for example, all sub-pixels at half-pixel locations, or a combination of sub-pixels at half-pixel and one quarter-pixel locations. In any case, after before-hand sub-pixel value interpolation, the interpolated sub-pixel values are stored in frame store 850, together with the original decoded pixel values. As subsequent macroblocks are decoded, before-hand interpolated and stored, a decoded frame, at least partially interpolated to sub-pixel resolution is progressively assembled in the frame store 850 and becomes available for use as a reference frame for motion compensated prediction.

In embodiments of the decoder which do not employ before-hand sub-pixel value interpolation, the decoded block of image information (i.e. pixel values) produced as a result of the inverse quantisation and inverse transform operations performed on the macroblock in blocks **820** and **830** is passed directly to frame store **850**. As subsequent macroblocks are decoded and stored, a decoded frame, having unit pixel resolution is progressively assembled in the frame store **850** and becomes available for use as a reference frame for motion compensated prediction.

When an INTER frame is decoded, the encoded video stream **725** is demultiplexed into encoded prediction error information **723** for each macroblock of the frame, associated motion coefficients **724** and control information. Again, the decoding process is performed macroblock-by-macroblock. When the encoded prediction error information **723** for a macroblock is extracted from the video stream **725** by MUX/DMUX unit **810**, it is passed to inverse quantiser **820**. Control manager **870** controls inverse quantiser **820** to apply a suitable level of inverse quantisation to the macroblock of encoded prediction error information, according to control information received in video stream **725**. The inverse quantised macroblock of prediction error information is then inversely transformed in the inverse DCT transformer **830** to yield decoded prediction error information for the macroblock.

The motion coefficients **724** associated with the macroblock in question are extracted from the video stream **725** by MUX/DMUX unit **810** and passed to motion compensated prediction block **840**, which reconstructs a motion vector for the macroblock using the same motion model as that used to encode the INTER-coded macroblock in encoder **700**. The reconstructed motion vector approximates the motion vector originally determined by motion estimation block **760** of the encoder. The motion compensated prediction block **840** of the decoder uses the reconstructed motion vector to identify the location of a block of pixel/sub-pixel values in a prediction reference frame stored in frame store **850**. The reference frame may be, for example, a previously decoded INTRA frame, or a previously decoded INTER frame. In either case, the block of pixel/sub-pixel values indicated by the reconstructed motion vector, represents the prediction of the macroblock in question.

The reconstructed motion vector may point to any pixel or sub-pixel. If the motion vector indicates that the prediction for the current macroblock is formed from pixel values (i.e. the values of pixels at unit pixel locations), these can simply be retrieved from frame store **850**, as the values in question are obtained directly during the decoding of each frame. If the motion vector indicates that the prediction for the current macroblock is formed from sub-pixel values, these must either be retrieved from frame store **850**, or calculated in on-demand sub-pixel interpolation block **890**. Whether sub-pixel values must be calculated, or can simply be retrieved from the frame store, depends on the degree of before-hand sub-pixel value interpolation used in the decoder.

In embodiments of the decoder that do not employ before-hand sub-pixel value interpolation, the required sub-pixel values are all calculated in on-demand sub-pixel value interpolation block **890**. On the other hand, in embodiments in which all sub-pixel values are interpolated before-hand, motion compensated prediction block **840** can retrieve the required sub-pixel values directly from the frame store **850**. In embodiments that use a combination before-hand and on-demand sub-pixel value interpolation, the action required in order to obtain the required sub-pixel values depends on which sub-pixel values are interpolated before-hand. Taking

as an example an embodiment in which all sub-pixel values at half-pixel locations are calculated before-hand, it is evident that if a reconstructed motion vector for a macroblock points to a pixel at unit location or a sub-pixel at half-pixel location, all the pixel or sub-pixel values required to form the prediction for the macroblock are present in the frame store **850** and can be retrieved from there by motion compensated prediction block **840**. If, however, the motion vector indicates a sub-pixel at a quarter-pixel location, the sub-pixels required to form the prediction for the macroblock are not present in frame store **850** and are therefore calculated in on-demand sub-pixel value interpolation block **890**. In this case, on-demand sub-pixel value interpolation block **890** retrieves any pixel or sub-pixel required to perform the interpolation from frame store **850** and applies the interpolation method described below. Sub-pixel values calculated in on-demand sub-pixel value interpolation block **890** are passed to motion compensated prediction block **840**.

Once a prediction for a macroblock has been obtained, the prediction (that is, a macroblock of predicted pixel values) is passed from motion compensated prediction block **840** to combiner **860** where it combined with the decoded prediction error information for the macroblock to form a reconstructed image block which, in turn, is passed to the video output **880** of the decoder.

It should be appreciated that in practical implementations of encoder **700** and decoder **800**, the extent to which frames are before-hand sub-pixel interpolated, and thus the amount of on-demand sub-pixel value interpolation that is performed, can be chosen according to, or dictated by, the hardware implementation of the video encoder **700**, or the environment in which it is intended to be used. For example, if the memory available to the video encoder is limited, or memory must be reserved for other functions, it is appropriate to limit the amount of before-hand sub-pixel value interpolation that is performed. In other cases, where the microprocessor performing the video encoding operation has limited processing capacity, e.g. the number of operations per second that can be executed is comparatively low, it is more appropriate to restrict the amount of on-demand sub-pixel value interpolation that is performed. In a mobile communications environment, for example, when video encoding and decoding functionality is incorporated in a mobile telephone or similar wireless terminal for communication with a mobile telephone network, both memory and processing power may be limited. In this case a combination of before-hand and on-demand sub-pixel value interpolation may be the best choice to obtain an efficient implementation in the video encoder. In video decoder **800**, use of before-hand sub-pixel value is generally not preferred, as it typically results in the calculation of many sub-pixel values that are not actually used in the decoding process. However, it should be appreciated that although different amounts of before-hand and on-demand interpolation can be used in the encoder and decoder in order to optimise the operation of each, both encoder and decoder can be implemented so as to use the same division between before-hand and on-demand sub-pixel value interpolation.

Although the foregoing description does not describe the construction of bi-directionally predicted frames (B-frames) in the encoder **700** and the decoder **800**, it should be understood that in embodiments of the invention, such a capability may be provided. Provision of such capability is considered within the ability of one skilled in the art.

An encoder **700** or a decoder **800** according to the invention can be realised using hardware or software, or using a suitable combination of both. An encoder or decoder implemented in software may be, for example, a separate program or a soft-

41

ware building block that can be used by various programs. In the above description and in the drawings, the functional blocks are represented as separate units, but the functionality of these blocks can be implemented, for example, in one software program unit.

The encoder **700** and decoder **800** can further be combined in order to form a video codec having both encoding and decoding functionality. In addition to being implemented in a multimedia terminal, such a codec may also be implemented in a network. A codec according to the invention may be a computer program or a computer program element, or it may be implemented at least partly using hardware.

The sub-pixel interpolation method used in the encoder **700** and decoder **800** according to the invention now be described in detail. The method will first be introduced at a general conceptual level and then two preferred embodiments will be described. In the first preferred embodiment, sub-pixel value interpolation is performed to $\frac{1}{4}$ pixel resolution and in the second the method is extended to $\frac{1}{8}$ pixel resolution.

It should be noted that interpolation must produce identical values in the encoder and the decoder, but its implementation should be optimized for both entities separately. For example, in an encoder according to the first embodiment of the invention in which sub-pixel value interpolation is performed to $\frac{1}{4}$ pixel resolution, it is most efficient to calculate $\frac{1}{2}$ resolution pixels before-hand and to calculate values for $\frac{1}{4}$ resolution sub-pixels in an on-demand fashion, only when they are needed during motion estimation. This has the effect of limiting memory usage while keeping the computational complexity/burden at an acceptable level. In the decoder, on the other hand, it is advantageous not to pre-calculate any of the sub-pixels. Therefore, it should be appreciated that a preferred embodiment of the decoder does not include before-hand sub-pixel value interpolation block **845** and all sub-pixel value interpolation is performed in on-demand sub-pixel value interpolation block **890**.

In the description of the interpolation method provided below, references are made to the pixel positions depicted in FIG. **14a**. In this figure pixels labelled A represent original pixels (that is, pixels residing at unit horizontal and vertical locations). Pixels labelled with other letters represent sub-pixels that are to be interpolated. The description that follows will adhere to the previously introduced conventions regarding the description of pixel and sub-pixel locations.

Next, the steps required to interpolate all sub-pixel positions are described:

Values for the $\frac{1}{2}$ resolution sub-pixels labelled b are obtained by first calculating an intermediate value b using a Kth order filter, according to:

$$b = \sum_{i=1}^K x_i A_i \quad (9)$$

where x_i is a vector of filter coefficients, A_i is a corresponding vector of original pixel values A situated at unit horizontal and unit vertical locations, and K is an integer which defines the order of the filter. Thus, equation 9 can be re-expressed as:

$$b = x_1 A_1 + x_2 A_2 + x_3 A_3 + \dots + x_{K-1} A_{K-1} + x_K A_K \quad (10)$$

The values of the filter coefficients x_i and the order of the filter K may vary from embodiment to embodiment. Equally, different coefficient values may be used in the calculation of different sub-pixels within an embodiment. In other embodiments, the values of filter coefficients x_i and the order of the

42

filter may depend on which of the $\frac{1}{2}$ resolution b sub-pixels is being interpolated. Pixels A_i are disposed symmetrically with respect to the $\frac{1}{2}$ resolution sub-pixel b being interpolated and are the closest neighbours of that sub-pixel. In the case of the $\frac{1}{2}$ resolution sub-pixel b situated at half horizontal and unit vertical location, pixels A_i are disposed horizontally with respect to b (as shown in FIG. **14b**). If the $\frac{1}{2}$ resolution sub-pixel b situated at unit horizontal and half vertical location is being interpolated, pixels A_i are disposed vertically with respect to b (as shown in FIG. **14c**).

A final value for $\frac{1}{2}$ resolution sub-pixel b is calculated by dividing intermediate value b by a constant scale₁, truncating it to obtain an integer number and clipping the result to lie in the range $[0, 2^n - 1]$. In alternative embodiments of the invention rounding may be performed instead of truncation. Preferably, constant scale₁ is chosen to be equal to the sum of filter coefficients x_i .

A value for the $\frac{1}{2}$ resolution sub-pixel labelled c is also obtained by first calculating an intermediate value c using an Mth order filter, according to:

$$c = \sum_{i=1}^M y_i b_i \quad (11)$$

where y_i is a vector of filter coefficients, b_i is a corresponding vector of intermediate values b_i in the horizontal or vertical direction. i.e.:

$$c = y_1 b_1 + y_2 b_2 + y_3 b_3 + \dots + y_{M-1} b_{M-1} + y_M b_M \quad (12)$$

The values of the filter coefficients y_i and the order of the filter M may vary from embodiment to embodiment. Equally, different coefficient values may be used in the calculation of different sub-pixels within an embodiment. Preferably, the b values are intermediate values for $\frac{1}{2}$ resolution sub-pixels b which are disposed symmetrically with respect to $\frac{1}{2}$ resolution sub-pixel c and are the closest neighbours of sub-pixel c. In an embodiment of the invention, the $\frac{1}{2}$ resolution sub-pixels b are disposed horizontally with respect to sub-pixel c, in an alternative embodiment they are disposed vertically with respect to sub-pixel c.

A final value of $\frac{1}{2}$ resolution sub-pixel c is computed by dividing intermediate value c by a constant scale₂, truncating it to obtain an integer number and clipping the result to lie in the range $[0, 2^n - 1]$. In alternative embodiments of the invention rounding may be performed instead of truncation. Preferably, constant scale₂ is equal to scale₁ * scale₁.

It should be noted that the use of intermediate values b in the horizontal direction leads to the same result as using intermediate values b in the vertical direction.

There are two alternatives for interpolating values for the $\frac{1}{4}$ resolution sub-pixels labelled h. Both involve linear interpolation along a diagonal line linking $\frac{1}{2}$ resolution sub-pixels neighbouring the $\frac{1}{4}$ resolution sub-pixel h being interpolated. In a first embodiment, a value for sub-pixel h is calculated by averaging the values of the two $\frac{1}{2}$ resolution sub-pixels b closest to sub-pixel h. In a second embodiment, a value for sub-pixel h is calculated by averaging the values of the closest pixel A and the closest $\frac{1}{2}$ resolution sub-pixel c. It should be appreciated that this provides the possibility of using different combinations of diagonal interpolations to determine the values for sub-pixels h within the confines of different groups of 4 image pixels A. However, it should also be realised that the same combination should be used in both the encoder and the decoder in order to produce identical interpolation results.

FIG. 15 depicts 4 possible choices of diagonal interpolation for sub-pixels h in adjacent groups of 4 pixels within an image. Simulations in the TML environment have verified that both embodiments result in similar compression efficiency. The second embodiment has higher complexity, since calculation of sub-pixel c requires calculation of several intermediate values. Therefore the first embodiment is preferred.

Values for $\frac{1}{4}$ resolution sub-pixels labelled d and g are calculated from the values of their nearest horizontal neighbours using linear interpolation. In other words, a value for $\frac{1}{4}$ resolution sub-pixel d is obtained by averaging values of its nearest horizontal neighbours, original image pixel A and $\frac{1}{2}$ resolution sub-pixel b. Similarly, a value for $\frac{1}{4}$ resolution sub-pixel g is obtained by taking the average of its two nearest horizontal neighbours, $\frac{1}{2}$ resolution sub-pixels b and c.

Values for $\frac{1}{4}$ resolution sub-pixels labelled e, f and i are calculated from the values of their nearest neighbours in the vertical direction using linear interpolation. More specifically, a value for $\frac{1}{4}$ resolution sub-pixel e is obtained by averaging the values of its two nearest vertical neighbours, original image pixel A and $\frac{1}{2}$ resolution sub-pixel b. Similarly, a value for $\frac{1}{4}$ resolution sub-pixel f is obtained by taking the average of its two nearest vertical neighbours, $\frac{1}{2}$ resolution sub-pixels b and c. In an embodiment of the invention, a value for $\frac{1}{4}$ resolution sub-pixel i is obtained in manner identical to that just described in connection with $\frac{1}{4}$ resolution sub-pixel f. However, in an alternative embodiment of the invention, and in common with the H.26 test models TML5 and TML6 previously described, $\frac{1}{4}$ resolution sub-pixel i is determined using the values of the four closest original image pixels, according to $(A_1 + A_2 + A_3 + A_4 + 2)/4$.

It should also be noted that in all cases where an average involving pixel and/or sub-pixel values is determined, the average may be formed in any appropriate manner. For example, the value for $\frac{1}{4}$ resolution sub-pixel d can be defined as $d = (A + b)/2$ or as $d = (A + b + 1)/2$. The addition of 1 to the sum of values for pixel A and $\frac{1}{2}$ resolution sub-pixel b has the effect of causing any rounding or truncation operation subsequently applied to round or truncate the value for d to the next highest integer value. This is true for any sum of integer values and may be applied to any of the averaging operations performed according to the method of the invention in order to control rounding or truncation effects.

It should be noted that the sub-pixel value interpolation method according to the invention provides advantages over each of TML5 and TML6.

In contrast to TML5, in which the values of some of the $\frac{1}{4}$ resolution sub-pixels depend on previously interpolated values obtained for other $\frac{1}{4}$ resolution sub-pixels, in the method according to the invention, all $\frac{1}{4}$ resolution sub-pixels are calculated from original image pixels or $\frac{1}{2}$ resolution sub-pixel positions using linear interpolation. Thus, the reduction in precision of those $\frac{1}{4}$ resolution sub-pixel values which occurs in TML5 due to the intermediate truncation and clipping of the other $\frac{1}{4}$ resolution sub-pixels from which they are calculated, does not take place in the method according to the invention. In particular, referring to FIG. 14a, $\frac{1}{4}$ resolution sub-pixels h (and sub-pixel i in one embodiment of the invention) are interpolated diagonally in order to reduce dependency on other $\frac{1}{4}$ -pixels. Furthermore, in the method according to the invention, the number of calculations (and therefore the number of processor cycles) required to obtain a value for those $\frac{1}{4}$ resolution sub-pixels in the decoder is reduced compared with TML5. Additionally, the calculation of any $\frac{1}{4}$ resolution sub-pixel value requires a number of calculations which is substantially similar to the number of calculations required to determine any other $\frac{1}{4}$ resolution sub-pixel value.

More specifically, in a situation where the required $\frac{1}{2}$ resolution sub-pixel values are already available, e.g. they have been calculated before-hand, the number of calculations required to interpolate a $\frac{1}{4}$ resolution sub-pixel value from the pre-calculated $\frac{1}{2}$ resolution sub-pixel values is the same as the number of calculations required to calculate any other $\frac{1}{4}$ resolution sub-pixel value from the available $\frac{1}{2}$ resolution sub-pixel values.

In comparison with TML6, the method according to the invention does not require high precision arithmetic to be used in the calculation of all sub-pixels. Specifically, as all of the $\frac{1}{4}$ resolution sub-pixel values are calculated from original image pixels or $\frac{1}{2}$ resolution sub-pixel values using linear interpolation, lower precision arithmetic can be used in their interpolation. Consequently, in hardware implementations of the inventive method, for example in an ASIC (Application Specific Integrated Circuit), the use of lower precision arithmetic reduces the number of components (e.g. gates) that must be devoted to the calculation of $\frac{1}{4}$ resolution sub-pixel values. This, in turn, reduces the overall area of silicon that must be dedicated to the interpolation function. As the majority of sub-pixels are, in fact, $\frac{1}{4}$ resolution sub-pixels (12 out of the 15 sub-pixels illustrated in FIG. 14a), the advantage provided by the invention in this respect is particularly significant. In software implementations, where sub-pixel interpolation is performed using the standard instruction set of a general purpose CPU (Central Processor Unit) or using a DSP (Digital Signal Processor), a reduction in the precision of the arithmetic required generally leads to an increase in the speed at which the calculations can be performed. This is particularly advantageous in 'low cost' implementations, in which it is desirable to use a general purpose CPU rather than any form of ASIC.

The method according to the invention provides still further advantages compared with TML5. As mentioned previously, in the decoder only 1 out of the 15 sub-pixel positions is required at any given time, namely that which is indicated by received motion vector information. Therefore, it is advantageous if the value of a sub-pixel in any sub-pixel location can be calculated with the minimum number of steps that result in a correctly interpolated value. The method according to the invention provides this capability. As mentioned in the detailed description provided above, $\frac{1}{2}$ resolution sub-pixel c can be interpolated by filtering in either the vertical or the horizontal direction, the same value being obtained for c regardless of whether horizontal or vertical filtering is used. The decoder can therefore take advantage of this property when calculating values for $\frac{1}{4}$ resolution sub-pixels f and g in such a way as to minimise the number of operations required in order to obtain the required values. For example, if the decoder requires a value for $\frac{1}{4}$ resolution sub-pixel f, $\frac{1}{2}$ resolution sub-pixel c should be interpolated in the vertical direction. If a value is required for $\frac{1}{4}$ resolution sub-pixel g, it is advantageous to interpolate a value for c in the horizontal direction. Thus, in general, it can be said that the method according to the invention provides flexibility in the way in which values are derived for certain $\frac{1}{4}$ resolution sub-pixels. No such flexibility is provided in TML5.

Two specific embodiments will now be described in detail. The first represents a preferred embodiment for calculating sub-pixels with up to $\frac{1}{4}$ pixel resolution, while in the second, the method according to the invention is extended to the calculation of values for sub-pixels having up to $\frac{1}{8}$ pixel resolution. For both embodiments a comparison is provided between the computational complexity/burden resulting from use of the method according to the invention and that which

would result from use of the interpolation methods according to TML5 and TML6 in equivalent circumstances.

The preferred embodiment for interpolating sub-pixels at $\frac{1}{4}$ pixel resolution will be described with reference to FIGS. 14a, 14b and 14c. In the following, it will be assumed that all image pixels and final interpolated values for sub-pixels are represented with 8-bits.

Calculation of $\frac{1}{2}$ resolution sub-pixels at i) half unit horizontal and unit vertical locations and ii) unit horizontal and half unit vertical locations.

1. A value for the sub-pixel at half unit horizontal and unit vertical location, that is $\frac{1}{2}$ resolution sub-pixel b in FIG. 14a, is obtained by first calculating intermediate value $b = (A_1 - 5A_2 + 20A_3 + 20A_4 - 5A_5 + A_6)$ using the values of the six pixels (A_1 to A_6) which are situated at unit horizontal and unit vertical locations in either the row or the column of pixels containing b and which are disposed symmetrically about b, as shown in FIGS. 14b and 14c. A final value for $\frac{1}{2}$ resolution sub-pixel b is calculated as $(b+16)/32$ where the operator / denotes division with truncation. The result is clipped to lie in the range [0, 255].

Calculation of $\frac{1}{2}$ resolution sub-pixels at half unit horizontal and half unit vertical locations.

2. A value for the sub-pixel at half unit horizontal and half unit vertical location, that is $\frac{1}{2}$ resolution sub-pixel c in FIG. 14a, is calculated as $c = (b_1 - 5b_2 + 20b_3 + 20b_4 - 5b_5 + b_6 + 512)/1024$ using the intermediate values b for the six closest $\frac{1}{2}$ resolution sub-pixels which are situated in either the row or the column of sub-pixels containing c and which are disposed symmetrically about c. Again, operator / denotes division with truncation and the result is clipped to lie in the range [0, 255]. As previously explained, using intermediate values b for $\frac{1}{2}$ resolution sub-pixels b in the horizontal direction leads to the same result as using intermediate values b for $\frac{1}{2}$ resolution sub-pixels b in the vertical direction. Thus, in an encoder according to the invention, the direction for interpolating $\frac{1}{2}$ resolution sub-pixels b can be chosen according to a preferred mode of implementation. In a decoder according to the invention, the direction for interpolating sub-pixels b is chosen according to which, if any, $\frac{1}{4}$ resolution sub-pixels will be interpolated using the result obtained for $\frac{1}{2}$ resolution sub-pixel c.

Calculation of $\frac{1}{4}$ resolution sub-pixels at i) quarter unit horizontal and unit vertical locations; ii) quarter unit horizontal and half unit vertical locations; iii) unit horizontal and quarter unit vertical locations; and iv) half unit horizontal and quarter unit vertical locations.

3. Values for $\frac{1}{4}$ resolution sub-pixels d, situated at quarter unit horizontal and unit vertical locations are calculated according to $d = (A+b)/2$ using the nearest original image pixel A and the closest $\frac{1}{2}$ resolution sub-pixel b in the horizontal direction. Similarly, values for $\frac{1}{2}$ resolution sub-pixels g, situated at quarter unit horizontal and half unit vertical locations are calculated according to $g = (b+c)/2$ using the two nearest $\frac{1}{2}$ resolution sub-pixels in the horizontal direction. In a similar manner, values for $\frac{1}{4}$ resolution sub-pixels e, situated at unit horizontal and quarter unit vertical locations, are calculated according to $e = (A+b)/2$ using the nearest original image pixel A and the closest $\frac{1}{2}$ resolution sub-pixel b in the vertical direction. Values for $\frac{1}{4}$ resolution sub-pixels f, situated at half unit horizontal and quarter unit vertical locations, are determined from $f = (b+c)/2$ using the two nearest $\frac{1}{2}$ resolution sub-pixel in the vertical direction. In all cases, operator / denotes division with truncation.

Calculation of $\frac{1}{4}$ resolution sub-pixels at quarter unit horizontal and quarter unit vertical locations.

4. Values for $\frac{1}{4}$ resolution sub-pixels h, situated at quarter unit horizontal and quarter unit vertical locations are calculated according to $h = (b_1 + b_2)/2$, using the two nearest $\frac{1}{2}$ resolution sub-pixels b in the diagonal direction. Again, operator / denotes division with truncation.

5. A value for the $\frac{1}{4}$ resolution sub-pixel labeled i is computed from $i = (A_1 + A_2 + A_3 + A_4 + 2)/4$ using the four nearest original pixels A. Once more, operator / denotes division with truncation.

10 An analysis of the computational complexity of the first preferred embodiment of the invention will now be presented.

In the encoder, it is likely that the same sub-pixel values will be calculated multiple times. Therefore, and as previously explained, the complexity of the encoder can be reduced by pre-calculating all sub-pixel values and storing them in memory. However, this solution increases memory usage by a large margin. In the preferred embodiment of the invention, in which motion vector accuracy is $\frac{1}{4}$ pixel resolution in both the horizontal and vertical dimensions, storing pre-calculated sub-pixel values for the whole image requires 16 times the memory required to store the original, non-interpolated image. To reduce memory usage, all $\frac{1}{2}$ resolution sub-pixels can be interpolated before-hand and $\frac{1}{4}$ resolution sub-pixels can be calculated on-demand, that is, only when they are needed. According to the method of the invention, on-demand interpolation of values for $\frac{1}{4}$ resolution sub-pixels only requires linear interpolation from $\frac{1}{2}$ resolution sub-pixels. Four times the original picture memory is required to store the pre-calculated $\frac{1}{2}$ resolution sub-pixels since only 8 bits are necessary to represent them.

However, if the same strategy of pre-calculating all $\frac{1}{2}$ resolution sub-pixels using before-hand interpolation is used in conjunction with the direct interpolation scheme of TML6, the memory requirements increase to 9 times the memory required to store the original non-interpolated image. This results from the fact that a larger number of bits is required to store the high precision intermediate values associated with each $\frac{1}{2}$ resolution sub-pixel in TML6. In addition, the complexity of sub-pixel interpolation during motion estimation is higher in TML6, since scaling and clipping has to be performed for every $\frac{1}{2}$ and $\frac{1}{4}$ sub-pixel location.

In the following, the complexity of the sub-pixel value interpolation method according to the invention, when applied in a video decoder, is compared with that of the interpolation schemes used in TML5 and TML6. Throughout the analysis which follows, it is assumed that in each method the interpolation of any sub-pixel value is performed using only the minimum number of steps required to obtain a correctly interpolated value. It is further assumed that each method is implemented in a block based manner, that is, intermediate values common for all the sub-pixels to be interpolated in a particular $N \times M$ block are calculated only once. An illustrative example is provided in FIG. 16. Referring to FIG. 16, it can be seen that in order to calculate a 4×4 block of $\frac{1}{2}$ resolution sub-pixels c, a 9×4 block of $\frac{1}{2}$ resolution sub-pixels b is first calculated.

Compared with the sub-pixel value interpolation method used in TML5, the method according to the invention has a lower computational complexity for the following reasons:

1. Unlike the sub-pixel value interpolation scheme used in TML5, according to the method of the invention, a value for $\frac{1}{2}$ resolution sub-pixel c can be obtained by filtering in either the vertical or the horizontal direction. Thus, in order to reduce the number of operations, $\frac{1}{2}$ resolution sub-pixel c can be interpolated in the vertical direction if a value for $\frac{1}{4}$ resolution sub-pixel f is required and in the horizontal direction if a value for $\frac{1}{4}$ resolution sub-pixel g is

required. As an example, FIG. 17 shows all the $\frac{1}{2}$ resolution sub-pixel values that must be calculated in order to interpolate values for $\frac{1}{4}$ resolution sub-pixels g in an image block defined by 4×4 original image pixels using the interpolation method of TML5 (FIG. 17a) and using the method according to the invention (FIG. 17b). In this example, the sub-pixel value interpolation method according to TML5 requires a total of $88\frac{1}{2}$ resolution sub-pixels to be interpolated, while the method according to the invention requires the calculation of $72\frac{1}{2}$ resolution sub-pixels. As can be seen from FIG. 17b, according to the invention, $\frac{1}{2}$ resolution sub-pixels c are interpolated in the horizontal direction in order to reduce the number of calculations required.

2. According to the method of the invention, $\frac{1}{4}$ resolution sub-pixel h is calculated by linear interpolation from its two closest neighbouring $\frac{1}{2}$ resolution sub-pixels in the diagonal direction. The respective numbers of $\frac{1}{2}$ resolution sub-pixels that must be calculated in order to obtain values for $\frac{1}{4}$ resolution sub-pixels h within a 4×4 block of original image pixels using the sub-pixel value interpolation method according to TML5 and the method according to the invention are shown in FIGS. 18(a) and 18(b), respectively. Using the method according to TML5 it is necessary to interpolate a total of $56\frac{1}{2}$ resolution sub-pixels, while according to the method of the invention it is necessary to interpolate $40\frac{1}{2}$ resolution sub-pixels.

Table 1 summarizes the decoder complexities of the three sub-pixel value interpolation methods considered here, that according to TML5, the direct interpolation method used in TML6 and the method according to the invention. Complexity is measured in terms of the number of 6-tap filtering and linear interpolation operations performed. It is assumed that Interpolation of $\frac{1}{4}$ resolution sub-pixel i is calculated according to $i = (A_1 + A_2 + A_3 + A_4 + 2)/4$ which is bilinear interpolation and effectively comprises two linear interpolation operations. The operations needed to interpolate sub-pixel values with one 4×4 block of original image pixels are listed for each of the 15 sub-pixel positions which, for convenience of reference, are numbered according to the scheme shown in FIG. 19. Referring to FIG. 19, location 1 is the location of an original image pixel A and locations 2 to 16 are sub-pixel locations. Location 16 is the location of $\frac{1}{4}$ resolution sub-pixel i. In order to compute the average number of operations it has been assumed that the probability of a motion vector pointing to each sub-pixel position is the same. The average complexity is therefore the average of the 15 sums calculated for each sub-pixel location and the single full-pixel location.

TABLE 1

Complexity of $\frac{1}{4}$ resolution sub-pixel interpolation in TML5, TML6 and the method according to the invention.						
Location	TML5		TML6		Inventive Method	
	linear.	6-tap	linear.	6-tap	linear.	6-tap
1	0	0	0	0	0	0
3, 9	0	16	0	16	0	16
2, 4, 5, 13	16	16	0	16	16	16
11	0	52	0	52	0	52
7, 15	16	52	0	52	16	52
10, 12	16	68	0	52	16	52
6, 8, 14	48	68	0	52	16	32
16	32	0	32	0	32	0
Average	19	37	2	32	13	28.25

It can be seen from Table 1 that the method according to the invention requires fewer 6-tap filter operations than the sub-

pixel value interpolation method according to TML6 and only a few additional linear interpolation operations. Since 6-tap filter operations are much more complex than linear interpolation operations the complexity of the two methods is similar. The sub-pixel value interpolation method according to TML5 has a considerably higher complexity.

The preferred embodiment for interpolating sub-pixels with up to $\frac{1}{8}$ pixel resolution will now be described with reference to FIGS. 20, 21 and 22.

FIG. 20 presents the nomenclature used to describe pixels, $\frac{1}{2}$ resolution sub-pixels, $\frac{1}{4}$ resolution sub-pixels and $\frac{1}{8}$ resolution sub-pixels in this extended application of the method according to the invention.

1. Values for the $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixels labelled b^1 , b^2 and b^3 in FIG. 20 are obtained by first calculating intermediate values $b^1 = (-3A_1 + 12A_2 - 37A_3 + 229A_4 + 71A_5 - 21A_6 + 6A_7 - A_8)$; $b^2 = (-3A_1 + 12A_2 - 39A_3 + 158A_4 + 158A_5 - 39A_6 + 12A_7 - 3A_8)$; and $b^3 = (-A_1 + 6A_2 - 21A_3 + 71A_4 + 229A_5 - 37A_6 + 13A_7 - 3A_8)$ using the values of the eight nearest image pixels (A_1 to A_8) situated at unit horizontal and unit vertical locations in either the row or the column containing b^1 , b^2 and b^3 and disposed symmetrically about $\frac{1}{2}$ resolution sub-pixel b^2 . The asymmetries in the filter coefficients used to obtain intermediate values b^1 and b^3 account for the fact that pixels A_1 to A_8 are not symmetrically located with respect to $\frac{1}{4}$ resolution sub-pixels b^1 and b^3 . Final values for sub-pixels b^i , $i=1, 2, 3$ are calculated according to $b^i = (b^i + 128)/256$ where the operator / denotes division with truncation. The result is clipped to lie in the range $[0, 255]$.

2. Values for the $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixels labelled c^{ij} , $i, j=1, 2, 3$, are calculated according to $c^{ij} = (-3b_1^j + 12b_2^j - 37b_3^j + 229b_4^j + 71b_5^j - 21b_6^j + 6b_7^j - b_8^j + 32768)/65536$; $c^{2j} = (-3b_1^j + 12b_2^j - 39b_3^j + 158b_4^j + 158b_5^j - 39b_6^j + 12b_7^j - 3b_8^j + 32768)/65536$ and $c^{3j} = (-b_1^j + 6b_2^j - 21b_3^j + 71b_4^j + 229b_5^j - 37b_6^j + 13b_7^j - 3b_8^j + 32768)/65536$ using the intermediate values b^1 , b^2 and b^3 calculated for the eight closest sub-pixels (b_1^j to b_8^j) in the vertical direction, sub-pixels b^j being situated in the column comprising the $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixels c^{ij} being interpolated and disposed symmetrically about the $\frac{1}{2}$ resolution sub-pixel c^{2j} . The asymmetries in the filter coefficients used to obtain values for sub-pixels c^{1j} and c^{3j} account for the fact that sub-pixels b_1^j to b_8^j are not symmetrically located with respect to $\frac{1}{4}$ resolution sub-pixels c^{1j} and c^{3j} . Once more, operator / denotes division with truncation. Before the interpolated values for sub-pixels c^{ij} are stored in the frame memory they are clipped to lie in the range $[0, 255]$. In an alternative embodiment of the invention, $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixels c^{ij} are calculated using in an analogous manner using intermediate values b^1 , b^2 and b^3 in the horizontal direction.

3. Values for $\frac{1}{8}$ resolution sub-pixels labelled d are calculated using linear interpolation from the values of their closest neighbouring image pixel, $\frac{1}{2}$ resolution or $\frac{1}{4}$ resolution sub-pixels in the horizontal or vertical direction. For example, upper leftmost $\frac{1}{8}$ resolution sub-pixel d is calculated according to $d = (A + b^1 + 1)/2$. As before, operator / indicates division with truncation.

4. Values for $\frac{1}{8}$ resolution sub-pixels labelled e and f are calculated using linear interpolation from the values of image pixels, $\frac{1}{2}$ resolution or $\frac{1}{4}$ resolution sub-pixels in the diagonal direction. For example, referring to FIG. 20, upper leftmost pixel $\frac{1}{8}$ resolution sub-pixel e is calculated according to $e = (b^1 + b^1 + 1)/2$. The diagonal direction to be used in the interpolation of each $\frac{1}{8}$ resolution sub-pixel in a first preferred embodiment of the invention, hereinafter

referred to as 'preferred method 1', is indicated in FIG. 21(a). Values for $\frac{1}{8}$ resolution sub-pixels labelled g are calculated according to $g=(A+3c^{22}+3)/4$. As always, operator / denotes division with truncation. In an alternative embodiment of the invention, hereinafter referred to as 'preferred method 2', computational complexity is further reduced by interpolating $\frac{1}{8}$ resolution sub-pixels f using linear interpolation from $\frac{1}{2}$ resolution sub-pixels b², that is, according to the relationship $f=(3b^2+b^2+2)/4$. The b² sub-pixel which is closer to f is multiplied by 3. The diagonal interpolation scheme used in this alternative embodiment of the invention is depicted in FIG. 21(b). In further alternative embodiments, different diagonal interpolation schemes can be envisaged.

It should be noted that in all cases where an average involving pixel and/or sub-pixel values is used in the determination of $\frac{1}{8}$ resolution sub-pixels, the average may be formed in any appropriate manner. The addition of 1 to the sum of values used in calculating such an average has the effect of causing any rounding or truncation operation subsequently applied to round or truncate the average in question to the next highest integer value. In alternative embodiments of the invention, the addition of 1 is not used.

As in the case of sub-pixel value interpolation to $\frac{1}{4}$ pixel resolution previously described, memory requirements in the encoder can be reduced by pre-calculating only a part of the sub-pixel values to be interpolated. In the case of sub-pixel

applied in a video decoder to calculate values for sub-pixels at up to $\frac{1}{8}$ pixel resolution, is compared with that of the interpolation schemes used in TML5 and TML6. As in the equivalent analysis for $\frac{1}{4}$ pixel resolution sub-pixel value interpolation described above, it is assumed that in each method the interpolation of any sub-pixel value is performed using only the minimum number of steps required to obtain a correctly interpolated value. It is also assumed that each method is implemented in a block based manner, such that intermediate values common for all the sub-pixels to be interpolated in a particular N×M block are calculated only once.

Table 2 summarizes complexities of the three interpolation methods. Complexity is measured in terms of the number of 8-tap filter and linear interpolation operations performed in each method. The table presents the number of operations required to interpolate each of the $63\frac{1}{8}$ resolution sub-pixels within one 4×4 block of original image pixels, each sub-pixel location being identified with a corresponding number, as illustrated in FIG. 22. In FIG. 22, location 1 is the location of an original image pixel and locations 2 to 64 are sub-pixel locations. When computing the average number of operations, it has been assumed that the probability of a motion vector pointing to each sub-pixel position is the same. The average complexity is thus the average of the 63 sums calculated for each sub-pixel location and the single full-pixel location.

TABLE 2

Complexity of $\frac{1}{8}$ resolution sub-pixel interpolation in TML5, TML6 and the method according to the invention. (Results shown separately for Preferred Method 1 and Preferred Method 2).

Average	64	290.25	0	197.75	48	214.75	48	192.75

value interpolation to $\frac{1}{8}$ pixel resolution, it is advantageous to calculate all $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixels beforehand and to compute values for $\frac{1}{8}$ resolution sub-pixels in an on-demand fashion, only when they are required. When this approach is taken, both the interpolation method according to TML5 and that according to the invention require 16 times the original picture memory to store the $\frac{1}{2}$ resolution and $\frac{1}{4}$ resolution sub-pixel values. However, if the direct interpolation method according to TML6 is used in the same way, intermediate values for the $\frac{1}{2}$ resolution and $\frac{1}{4}$ pixel resolution sub-pixels must be stored. These intermediate values are represented with 32-bit precision and this results in a memory requirement 64 times that for the original, non-interpolated image.

In the following, the complexity of the sub-pixel value interpolation method according to the invention, when

As can be seen from Table 2, the number of 8-tap filtering operations performed according to preferred methods 1 and 2 are, respectively, 26% and 34% lower than the number of 8-tap filtering operation performed in the sub-pixel value interpolation method of TML5. The number of linear operations is 25% lower, in both preferred method 1 and preferred method 2, compared with TML5, but this improvement is of lesser importance compared to the reduction in 8-tap filtering operations. It can further be seen that the direct interpolation method used in TML6 has a complexity comparable that of both preferred methods 1 and 2 when used to interpolate values for $\frac{1}{8}$ resolution sub-pixels.

In view of the foregoing description it will be evident to a person skilled in the art that various modifications may be made within the scope of the invention. While a number of preferred embodiments of the invention have been described

in detail, it should be apparent that many modifications and variations thereto are possible, all of which fall within the true spirit and scope of the invention.

The invention claimed is:

1. A method for sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the method comprising causing an apparatus to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

2. A method according to claim 1, comprising causing the apparatus to use a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, wherein when the chosen weighted average is that involving the value of a nearest neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, causing the apparatus to select the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the nearest-neighbouring pixel and the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ to the sub-pixel having co-ordinates with odd values of K and L whose value is being interpolated.

3. A method according to claim 2, comprising causing the apparatus to use first and second weights with equal values when the nearest-neighbouring pixel and sub-pixel pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ are equidistant from the sub-pixel having co-ordinates with odd values of K and L whose value is being interpolated.

4. A method according to claim 1, comprising causing the apparatus to use a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, wherein when the chosen weighted average is that involving the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, causing the apparatus to select the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the sub-pixels having co-ordinates with even values of K and L to the sub-pixel having co-ordinates with odd values of K and L whose value is being interpolated.

5. A method according to claim 4, comprising causing the apparatus to use first and second weights with equal values when the sub-pixels having co-ordinates with even values of K and L are equidistant from the sub-pixel having co-ordinates with odd values of K and L whose value is being interpolated.

6. A method according to claim 1, comprising causing the apparatus to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an even value and L equal to an odd value is also required.

7. A method according to claim 1, comprising causing the apparatus to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an odd value and L equal to an even value is also required.

8. A method according to claim 1, comprising causing the apparatus to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an odd value O and L equal to an even value E, not including zero or 2^N , by taking an average of the value of a first sub-pixel having co-ordinates with K equal to the even value O-1 and L equal to E and a second sub-pixel having co-ordinates with K equal to the even value O+1 and L equal to E.

9. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2 and L equal to zero.

10. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to zero.

11. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2 and L equal to 2^N .

53

12. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to 2^N .

13. A method according to claim 1, comprising causing the apparatus to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value E, not including zero or 2^N , and L equal to an odd value O, by taking an average of the value of a first sub-pixel having co-ordinates with K equal to E and L equal to the even value O-1 and a second sub-pixel having co-ordinates with K equal to E and L equal to the even value O+1.

14. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to zero and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

15. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2.

16. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to zero and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to zero and L equal to 2^N-2 .

17. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-2 .

18. A method according to claim 1, comprising causing the apparatus to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N-1 , by taking a weighted average of the values of the four corner pixels that define the rectangular bounded region.

19. A method according to claim 1, in which N is one of the values 2, 3, and 4.

20. A method according to claim 1, wherein the pixels have a predetermined dynamic range, said predetermined dynamic range corresponding to the range of values said pixels can take.

21. A method according to claim 20, comprising interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and for sub-pixels having co-ordinates with K equal to zero and L equal to an even value, using weighted sums of the values of pixels located in rows and columns respectively, to produce a first intermediate value, said first intermediate value having a dynamic range equal to the predetermined dynamic range of the pixels used in said weighted sum multiplied by a value equal to the sum of the respective weights used in said weighted sum.

22. A method according to claim 21, wherein the dynamic range of said first intermediate value is defined by the number of bits used to represent the respective pixels used in said weighted sum plus the number of bits required to represent the sum of the respective weights used in said weighted sum.

23. A method according to claim 21, comprising truncating the first intermediate value by mathematically dividing the

54

first intermediate value by a first scale factor, said first scale factor having a value equal to the sum of the respective weights used in said weighted sum, thereby forming a sub-pixel value with a dynamic range equal to the predetermined dynamic range of said pixels.

24. A method according to claim 23, comprising using a truncated first intermediate sub-pixel value when interpolating a value for a sub-pixel having co-ordinates with odd values of K and L.

25. A method according to claim 21, comprising interpolating sub-pixel values for sub-pixels having co-ordinates with even values of K and L, using a weighted sum comprising first intermediate values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and corresponding first intermediate values for sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, to produce a second intermediate value, said second intermediate value having a dynamic range equal to the dynamic range of the first intermediate values used in said weighted sum, multiplied by a value equal to the sum of the respective weights used in said weighted sum.

26. A method according to claim 25, comprising truncating the second intermediate value by mathematically dividing the second intermediate value by a second scale factor, said second scale factor having a value equal to the sum of the respective weights used in the weighted sum of claim 21 multiplied by the sum of the respective weights used in the weighted sum of claim 25, thereby forming a sub-pixel value with a dynamic range equal to the predetermined dynamic range of said pixels.

27. A method according to claim 26, comprising using a truncated second intermediate sub-pixel value when interpolating a value for a sub-pixel having co-ordinates with odd values of K and L.

28. A method according to claim 21, comprising interpolating sub-pixel values for sub-pixels having co-ordinates with even values of K and L, using a weighted sum comprising first intermediate values for sub-pixels having co-ordinates with K equal to zero and L equal to an even value and corresponding first intermediate values for sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions to produce a second intermediate value, said second intermediate value having a dynamic range equal to the dynamic range of the first intermediate values used in said weighted sum, multiplied by a value equal to the sum of the respective weights used in said weighted sum.

29. A method according to claim 28, comprising truncating the second intermediate value by mathematically dividing the second intermediate value by a second scale factor, said second scale factor having a value equal to the sum of the respective weights used in the weighted sum of claim 21 multiplied by the sum of the respective weights used in the weighted sum of claim 28, thereby forming a sub-pixel value with a dynamic range equal to the dynamic range of said pixels.

30. A method according to claim 29, comprising using a truncated second intermediate sub-pixel value when interpolating a value for a sub-pixel having co-ordinates with odd values of K and L.

31. A method for quarter resolution sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation K/4, L/4, K and L being

55

positive integers having respective values between zero and 4, the method comprising causing an apparatus to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with K and L equal to 1 or 3, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{3}{4}$, $\frac{3}{4}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with K and L equal to zero, 2 or 4, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{3}{4}$, $\frac{3}{4}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to 2 and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to 2, used in the interpolation of the sub-pixels having co-ordinates with K and L equal to 1 or 3, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate a sub-pixel value for the sub-pixel having co-ordinates with both K and L equal to 2, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with K and L equal to 1 or 3, using a predetermined choice of either a weighted sum of the values of the sub-pixel having co-ordinates with K equal to 2 and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the value of the sub-pixel having co-ordinates with K equal to zero and L equal to 2 and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

32. A method for eighth resolution sub-pixel value interpolation to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically with the rectangular bounded region using the co-ordinate notation $K/8$, $L/8$, K and L being positive integers having respective values between zero and 8, the method comprising causing an apparatus to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with K and L equal to 1, 3, 5 or 7, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{4}{8}$, $\frac{4}{8}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with K and L equal to zero, 2, 4, 6 or 8, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{4}{8}$, $\frac{4}{8}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to 2, 4 or 6 and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to 2, 4 or 6, used in the interpolation of the sub-pixels having co-ordinates with K and L equal to 1, 3, 5 or 7, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with K and L equal to 2, 4 or 6, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with K and L equal to 1, 3, 5 or 7, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to

56

2, 4 or 6 and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to 2, 4 or 6 and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

33. An interpolator for sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

34. An interpolator according to claim 33, wherein the interpolator is configured to use a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, wherein when the chosen weighted average is that involving the value of a nearest neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, the interpolator is configured to select the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the nearest-neighbouring pixel and the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ to the sub-pixel having co-ordinates with odd values of K and L whose value is being interpolated.

35. An interpolator according to claim 34, wherein the interpolator is configured to use first and second weights with equal values when the nearest-neighbouring pixel and sub-

57

pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ are equidistant from the sub-pixel having co-ordinates with odd values of K and L whose value is being interpolated.

36. An interpolator according to claim 33, wherein the interpolator is configured to use a first and a second weight in the weighted average chosen to interpolate the sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, wherein when the chosen weighted average is that involving the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, the interpolator is configured to select the relative magnitudes of the first and second weights to be inversely proportional to the respective straight-line diagonal distances of the sub-pixels having co-ordinates with even values of K and L to the sub-pixel having co-ordinates with odd values of K and L whose value is being interpolated.

37. An interpolator according to claim 36, wherein the interpolator is configured to use first and second weights with equal values when the sub-pixels having co-ordinates with even values of K and L are equidistant from the sub-pixel having co-ordinates with odd values of K and L whose value is being interpolated.

38. An interpolator according to claim 33, wherein the interpolator is configured to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an even value and L equal to an odd value is also required.

39. An interpolator according to claim 33, wherein the interpolator is configured to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions when the value of a sub-pixel having co-ordinates with K equal to an odd value and L equal to an even value is also required.

40. A method according to claim 33, comprising truncating the second intermediate value by mathematically dividing the second intermediate value by a second scale factor, said second scale factor having a value equal to the sum of the respective weights used in the weighted sum of claim 63 multiplied by the sum of the respective weights used in the weighted sum of claim 67, thereby forming a sub-pixel value with a dynamic range equal to the dynamic range of said pixels.

41. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2 and L equal to zero.

42. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to zero, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to zero.

58

43. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2 and L equal to 2^N .

44. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N-2 and L equal to 2^N .

45. An interpolator according to claim 33, wherein the interpolator is configured to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value E, not including zero or 2^N , and L equal to an odd value O, by taking an average of the value of a first sub-pixel having co-ordinates with K equal to E and L equal to the even value O-1 and a second sub-pixel having co-ordinates with K equal to E and L equal to the even value O+1.

46. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to zero and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to zero, and a sub-pixel having co-ordinates with K equal to zero and L equal to 2.

47. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 1, by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to zero, and a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2.

48. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to zero and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to zero and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to zero and L equal to 2^N-2 .

49. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-1 , by taking an average of the value of a pixel having co-ordinates with K equal to 2^N and L equal to 2^N , and a sub-pixel having co-ordinates with K equal to 2^N and L equal to 2^N-2 .

50. An interpolator according to claim 33, wherein the interpolator is configured to interpolate a sub-pixel value for the sub-pixel having co-ordinates with K equal to 2^N-1 and L equal to 2^N-1 , by taking a weighted average of the values of the four corner pixels that define the rectangular bounded region.

51. An interpolator according to claim 33, wherein N is set equal to 2.

52. An interpolator according to claim 33, wherein N is set equal to 3.

53. An interpolator according to claim 33, wherein the pixels have a predetermined dynamic range, said predetermined dynamic range corresponding to the range of values said pixels can take.

54. An interpolator according to claim 53, wherein the interpolator is configured to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value

59

and L equal zero and for sub-pixels having co-ordinates with K equal to zero and L equal to an even value, using weighted sums of the values of pixels located in rows and columns respectively, to produce a first intermediate value, said first intermediate value having a dynamic range equal to the predetermined dynamic range of the pixels used in said weighted sum multiplied by a value equal to the sum of the respective weights used in said weighted sum.

55. An interpolator according to claim 54, wherein the dynamic range of said first intermediate value is defined by the number of bits used to represent the respective pixels used in said weighted sum plus the number of bits required to represent the sum of the respective weights used in said weighted sum.

56. An interpolator according to claim 54, wherein the interpolator is configured to truncate the first intermediate value by mathematically dividing the first intermediate value by a first scale factor, said first scale factor having a value equal to the sum of the respective weights used in said weighted sum, thereby forming a sub-pixel value with a dynamic range equal to the predetermined dynamic range of said pixels.

57. An interpolator according to claim 56, wherein the interpolator is configured to use a truncated first intermediate sub-pixel value when interpolating a value for a sub-pixel having co-ordinates with odd values of K and L.

58. An interpolator according to claim 54, wherein the interpolator is configured to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, using a weighted sum comprising first intermediate values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and corresponding first intermediate values for sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, to produce a second intermediate value, said second intermediate value having a dynamic range equal to the dynamic range of the first intermediate values used in said weighted sum, multiplied by a value equal to the sum of the respective weights used in said weighted sum.

59. An interpolator according to claim 58, wherein the interpolator is configured to truncate the second intermediate value by mathematically dividing the second intermediate value by a second scale factor, said second scale factor having a value equal to the sum of the respective weights used in the weighted sum of claim 54 multiplied by the sum of the respective weights used in the weighted sum of claim 58, thereby forming a sub-pixel value with a dynamic range equal to the predetermined dynamic range of said pixels.

60. An interpolator according to claim 59, wherein the interpolator is configured to use a truncated second intermediate sub-pixel value when interpolating a value for a sub-pixel having co-ordinates with odd values of K and L.

61. An interpolator according to claim 54, wherein the interpolator is configured to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, using a weighted sum comprising first intermediate values for sub-pixels having co-ordinates with K equal to zero and L equal to an even value and corresponding first intermediate values for sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded region to produce a second intermediate value, said second intermediate value having a dynamic range equal to the dynamic range of the first intermediate values used in said weighted sum, multiplied by a value equal to the sum of the respective weights used in said weighted sum.

62. An interpolator according to claim 61, wherein the interpolator is configured to truncate the second intermediate

60

ate value by mathematically dividing the second intermediate value by a second scale factor, said second scale factor having a value equal to the sum of the respective weights used in the weighted sum of claim 54 multiplied by the sum of the respective weights used in the weighted sum of claim 61, thereby forming a sub-pixel value with a dynamic range equal to the predetermined dynamic range of said pixels.

63. An interpolator according to claim 62, wherein the interpolator is configured to use a truncated second intermediate sub-pixel value when interpolating a value for a sub-pixel having co-ordinates with odd values of K and L.

64. A video encoder comprising an interpolator for sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent bounded rectangular regions.

65. A codec comprising a video encoder according to claim 64 and a video decoder comprising an interpolator for sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and

61

2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

66. A communications terminal comprising a video encoder according to claim 64.

67. A communications terminal according to claim 66, wherein the communications terminal is a wireless terminal.

68. A still image encoder comprising an interpolator for sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of

62

the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

69. A codec comprising a still image encoder according to claim 68 and a still image decoder comprising an interpolator for sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

70. A communications terminal comprising a still image encoder according to claim 68.

71. A video encoder comprising an interpolator for sub-pixel value interpolation, the interpolator being configured to

63

determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded region.

72. A communications terminal comprising a video decoder according to claim 71.

73. A still image decoder comprising an interpolator for sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant

64

being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

74. A communications terminal comprising a still image decoder according to claim 73.

75. An interpolator for sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator comprising:

circuitry configured to interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

circuitry configured to interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

circuitry configured to interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even

65

value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

76. An interpolator for quarter resolution sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/4$, $L/4$, K and L being positive integers having respective values between zero and 4, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with K and L equal to 1 or 3, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $3/4$, $3/4$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with K and L equal to zero, 2 or 4, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $3/4$, $3/4$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to 2 and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to 2, used in the interpolation of the sub-pixels having co-ordinates with K and L equal to 1 or 3, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate a sub-pixel value for the sub-pixel having co-ordinates with both K and L equal to 2, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with both K and L equal to 1 or 3, using a predetermined choice of either a weighted sum of the values of the sub-pixel having co-ordinates with K equal to 2 and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the value of the sub-pixel having co-ordinates with K equal to zero and L equal to 2 and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

77. A video encoder or still image encoder comprising an interpolator according to claim 76.

78. A communications terminal comprising a video encoder or still image encoder according to claim 77.

79. An interpolator for eighth resolution sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/8$, $L/8$, K and L being positive integers having respective values between zero and 8, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with K and L equal to 1, 3, 5 or 7, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $7/8$, $7/8$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with both K and

66

L equal to zero, 2, 4, 6 or 8, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $7/8$, $7/8$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to 2, 4 or 6 and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to 2, 4 or 6, used in the interpolation of the sub-pixels having co-ordinates with both K and L equal to 1, 3, 5 or 7, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with K and L equal to 2, 4 or 6, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with K and L equal to 1, 3, 5 or 7, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to 2, 4 or 6 and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to 2, 4 or 6 and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

80. A video decoder or still image decoder comprising an interpolator according to claim 79.

81. A communications terminal comprising a video decoder or still image decoder according to claim 80.

82. A computer program for sub-pixel value interpolation, embodied on a computer readable storage medium, the computer program being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the computer program comprising:

computer program code for interpolating a sub-pixel value for a sub-pixel having co-ordinates with odd values of both K and L , according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $1/2$, $1/2$, or a weighted average of the values of a pair of diagonally-opposed sub-pixels having co-ordinates with even values of both K and L , including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $1/2$, $1/2$ and the nearest neighbouring pixel;

computer program code for interpolating sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L , using weighted sums of the values of pixels located in rows and columns respectively; and

computer program code for interpolating sub-pixel values for sub-pixels having co-ordinates with even values of K and L , used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L , using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with

67

K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

83. A network apparatus comprising an interpolator for sub-pixel value interpolation, the interpolator being configured to determine values for sub-pixels situated within a rectangular bounded region defined by four corner pixels with no intermediate pixels between the corners, the pixels and sub-pixels being configured for display in rows and columns, pixel and sub-pixel locations in the rows and columns being representable mathematically within the rectangular bounded region using the co-ordinate notation $K/2^N$, $L/2^N$, K and L being positive integers having respective values between zero and 2^N , N being a positive integer greater than one and representing a particular degree of sub-pixel value interpolation, the interpolator being configured to:

interpolate a sub-pixel value for a sub-pixel having co-ordinates with odd values of K and L, according to a predetermined choice of either a weighted average of the value of a nearest-neighbouring pixel and the value of the sub-pixel situated at co-ordinates $\frac{1}{2}$, $\frac{1}{2}$, or a weighted average of the values of a pair of diagonally-

68

opposed sub-pixels having co-ordinates with even values of K and L, including zero, situated within a quadrant of the rectangular bounded region, the quadrant being defined by the sub-pixel having co-ordinates $\frac{1}{2}$, $\frac{1}{2}$ and the nearest neighbouring pixel;

interpolate sub-pixel values for sub-pixels having co-ordinates with K equal to an even value and L equal to zero and sub-pixels having co-ordinates with K equal to zero and L equal to an even value, used in the interpolation of the sub-pixels having co-ordinates with odd values of K and L, using weighted sums of the values of pixels located in rows and columns respectively; and

interpolate sub-pixel values for sub-pixels having co-ordinates with even values of K and L, used in the interpolation of sub-pixel values for the sub-pixels having co-ordinates with odd values of K and L, using a predetermined choice of either a weighted sum of the values of sub-pixels having co-ordinates with K equal to an even value and L equal to zero and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions, or a weighted sum of the values of sub-pixels having co-ordinates with K equal to zero and L equal to an even value and the values of sub-pixels having corresponding co-ordinates in immediately adjacent rectangular bounded regions.

(57) **ABSTRACT**

A method and system for image coding, wherein an image is divided into a plurality of blocks for scanning. The pixels values in the scanned block are represented by a plurality of level-run value pairs, wherein the level value is indicative of a non-zero pixel value and the run value is indicative of the number of consecutive zero pixel values preceding the non-zero pixel value. A plurality of contexts indicative of the level-run value pairs are conveyed to a decoder for allowing the decoder to reconstruct the image based on the contexts. The assignment of the contexts is also based on the level value of a preceding level-run pair. Additionally, instead of an end-of-block symbol, the number of non-zero coefficients is provided to the decoder prior to conveying the contexts thereto.

METHOD AND SYSTEM FOR CONTEXT-BASED ADAPTIVE BINARY ARITHMETIC CODING

This patent application is based on and claims priority to U.S. Provisional Application No. 60/322,112, filed Sep. 14, 2001.

FIELD OF THE INVENTION

The present invention relates generally to the compression of still images and video sequences and, more particularly, to a method and system for context-based adaptive binary arithmetic coding.

BACKGROUND OF THE INVENTION

A digital image in uncompressed form comprises an array of image pixels or picture elements. For example, in a commonly used digital image format, known as the Quarter Common Interchange Format (QCIF), an image, or frame, comprises 25,344 pixels arranged in an array 176×144 pixels. Each pixel, in turn, is represented by a certain number of bits, which carry information about the brightness (luminance) and/or color (chrominance) of the pixel. Different schemes exist for representing the luminance and/or chrominance of pixels in a digital image. Commonly, a so-called YUV color model is used. The luminance, or Y, component represents the luminance of the pixel, while the color of the pixel is represented by two chrominance or color difference components, labelled U and V. Other color models, such as RGB (Red, Green, Blue) color models, which are based on components representing the three primary colors of light, are also commonly used. However, color models based on a luminance/chrominance representation provide advantages compared with color models based on primary colors. These stem from the nature of the human visual system, which is more sensitive to intensity variations than it is to color variations. YUV color models typically exploit this property by using a lower spatial resolution for the chrominance components (U, V) than for the luminance component (Y). In this way the amount of information needed to represent the color information in an image can be reduced without a noticeable reduction in perceived image quality.

The lower spatial resolution of the chrominance components is usually attained by sub-sampling. Typically, a block of 16×16 image pixels is represented by four blocks of 8×8 pixels comprising luminance information and the corresponding chrominance components are each represented by one block of 8×8 pixels representing an area of the image equivalent to that of the 16×16 pixels in the luminance component. The chrominance components are thus spatially sub-sampled by a factor of 2 in the x and y directions. The resulting assembly of four 8×8 pixel luminance blocks and two spatially corresponding 8×8 pixel chrominance blocks is commonly referred to as a YUV macroblock, or macroblock, for short. A QCIF image comprises 11×9 such macroblocks. If the luminance blocks and chrominance blocks are represented with 8 bit resolution (that is by numbers in the range 0 to 255), the total number of bits required to represent the luminance and chrominance information associated with each macroblock is $6 \times (8 \times 8 \times 8) = 3072$ bits. Thus, the number of bits needed to represent an image in QCIF format is $99 \times 3072 = 304,128$ bits.

It should be appreciated that even in the situation described above, where both chrominance components of a digital color image are sub-sampled by a factor of two, an

2

uncompressed image of only moderate size (e.g. 176×144 pixels) requires a large number of bits for its representation. This means that the amount of memory required to store digital images in uncompressed form is excessive. Furthermore, if still images are to be transferred, for example over a data communications network having a moderate or low available bandwidth, transmission times may become lengthy, or the network may become congested. Bandwidth requirements are even more severe if it is desired to transmit a series of images as a digital video sequence in real time. For example, transmission of a digital video sequence comprising a series of images in uncompressed QCIF format, represented using a YUV color model, at a rate of 30 frames per second, requires more than 9 Mbits/s (million bits per second). Such a high data rate is generally impractical for use in video recording, transmission and display applications because of the very large storage capacity, transmission channel capacity and hardware performance required. If a video sequence is to be transmitted in real-time over a fixed line network such as an ISDN (Integrated Services Digital Network) or a PSTN (Public Service Telephone Network), the available data transmission bandwidth is typically of the order of 64 kbits/s. In mobile video-telephony, where transmission takes place at least in part over a radio communications link, the available bandwidth can be as low as 20 kbits/s. This means that a significant reduction in the amount of information used to represent video data must be achieved in order to enable transmission of digital images or video sequences over low bandwidth communication networks. It is nevertheless desirable that this reduction should be achieved without significantly degrading the quality of the images/video sequence.

Over the past years, a considerable amount of research work has been directed towards reducing the amount of data required to represent digital images and video sequences, resulting in the development of numerous different schemes and international standards for compressing digital still images and digital video. The basic approach to image compression used in almost all still image and video encoders existing today involves block-based transform coding. Typically, transform coding translates image data from a representation comprising pixel values to a form comprising a set of coefficient values, each of which is a weighting factor (multiplier) for a basis function of the transform in question. It can be shown that there is a considerable degree of spatial redundancy within a typical digital image. In practical terms, this means that in general the value of any pixel within an image is substantially the same as the value of other pixels in its immediate vicinity; that is, there is a significant degree of correlation between pixel values. It is further known that when certain mathematical transformations, such as the two-dimensional Discrete Cosine Transform (DCT), are performed on image data, this spatial redundancy is reduced significantly, thereby producing a more compact representation of the image data. Block-based Transform Coding as Used in JPEG Still Image Coding

In still image compression, such as that performed according to the baseline mode of the widely-used JPEG standard, an image to be coded is first divided into an array of non-overlapping square blocks, each block comprising, for example, an 8×8 array of image pixels. In the case of the JPEG baseline, a two-dimensional Discrete Cosine Transform (DCT) is then applied independently to each of the image blocks. This has the effect of converting the image data from the pixel value domain to the spatial frequency

domain and to produce a corresponding set of coefficient values, each of which is a weighting factor for a basis function of the two-dimensional DCT. The coefficient values thus produced are quantized and then coded in a lossless manner using entropy coding to further reduce the amount of data (i.e. number of bits) required for their representation. According to the JPEG baseline, the entropy coder employs only Huffman coding to produce a compressed bit-stream, although in other modes arithmetic coding may alternatively be used. Finally, data describing image and coding parameters (e.g. type of compression, quantization and coding tables, image size, etc.) is embedded in the bit-stream produced by the entropy encoder. As the JPEG standard comprises four alternative coding modes and places few constraints on the quantization and coding tables that can be used, this is necessary in order to enable JPEG compressed bit-streams to be interchanged among different platforms and for images to be reconstructed without any ambiguity.

A digital video sequence, like an ordinary motion picture recorded on film, comprises a sequence of still images (often referred to as 'frames'), the illusion of motion being created by displaying the frames one after the other at a relatively fast rate, typically 15 to 30 frames per second. As in any still image, the pixel values of an individual frame within a digital video sequence exhibit considerable spatial redundancy. Therefore, the frames of a digital video sequence are amenable to block-based transform coding, just like individual still images.

Images in the consecutive frames of a video sequence also tend to be quite similar and thus the overall change between one video frame and the next is rather small. This means that there is considerable temporal redundancy within a typical digital video sequence. For example, a scene may comprise some stationary elements, such as background scenery, and some moving areas, for example the face of a newsreader. In consecutive frames of the sequence, it is likely that the background will remain unaltered and the only movement in the scene will be due to changes in facial expression of the newsreader. Thus, when forming a compressed representation of a video sequence there is also a possibility to use techniques which reduce the temporal redundancy of the image data of the sequence in addition to methods that reduce spatial redundancy, thereby allowing further data compression to be achieved.

Hybrid Video Encoder/Decoder

State of the art video coding systems make use of a technique known as 'motion-compensated prediction', to reduce the temporal redundancy in video sequences. Using motion-compensated prediction, the image content of some (often many) frames in a digital video sequence is 'predicted' from one or more other frames in the sequence, known as 'reference frames'. Prediction of image content is achieved by tracing the motion of objects or regions of an image between a frame to be coded (compressed) and the reference frame(s) using 'motion vectors'. In general, the reference frame(s) may precede the frame to be coded or may follow it in the video sequence. However, as will become apparent from discussions later in the text, it is not appropriate (or possible) to apply motion-compensated prediction to all frames of a video sequence and thus at least two types of encoding are used in state of the art video coding systems.

Frames of a video sequence which are compressed using motion-compensated prediction are generally referred to as INTER-coded or P-frames. Motion-compensated prediction alone rarely provides a sufficiently precise representation of the image content of a video frame and therefore it is

typically necessary to provide a so-called 'prediction error' (PE) frame with each INTER-coded frame. As will be explained in greater detail later in the text, the prediction error frame represents the difference between a decoded version of the INTER-coded frame and the image content of the frame to be coded. More specifically, the prediction error frame comprises values that represent the difference between pixel values in the frame to be coded and corresponding reconstructed pixel values formed on the basis of a predicted (INTER-coded) version of the frame in question. Consequently, the prediction error frame has characteristics similar to a still image and block-based transform coding can be applied in order to reduce the amount of data (number of bits) required to represent it.

Frames of a video sequence which are not compressed using motion-compensated prediction are referred to as INTRA-coded or I-frames. Generally, INTRA-coded frames are produced by applying block-based transform coding directly to the pixel values of the frame to be coded. Additionally, where possible, blocks of INTRA-coded frames are predicted from previously coded blocks within the same frame. This technique, known as INTRA-prediction, has the effect of further reducing the amount of data required to represent an INTRA-coded frame.

In order to illustrate principles of block-based transform coding and motion-compensated prediction in greater detail, reference will now be made to FIG. 1, which is a schematic of a generic hybrid video encoder that employs a combination of INTRA- and INTER-coding to produce a compressed (encoded) video bit-stream. A corresponding decoder is illustrated in FIG. 2 and will be described later in the text.

The video encoder 300 comprises an input 301 for receiving a digital video signal from a camera or other video source (not shown). It also comprises a transformation unit 304 which is arranged to perform a block-based discrete cosine transform (DCT), a quantizer 306, an inverse quantizer 308, an inverse transformation unit 310, arranged to perform an inverse block-based discrete cosine transform (IDCT), combiners 312 and 316, and a frame store 320. The encoder further comprises a motion estimator 330, a motion field coder 340 and a motion compensated predictor 350. Switches 302 and 314 are operated co-operatively by control manager 360 to switch the encoder between an INTRA-mode of video encoding and an INTER-mode of video encoding. The encoder 300 also comprises a video multiplex coder 370 which forms a single bit-stream from the various types of information produced by the encoder 300 for further transmission to a remote receiving terminal or, for example, for storage on a mass storage medium, such as a computer hard drive (not shown).

Encoder 300 operates as follows. Each frame of uncompressed video provided from the video source to input 301 is received and processed macroblock-by-macroblock, preferably in raster-scan order. When the encoding of a new video sequence starts, the first frame of the sequence is encoded as an INTRA-coded frame. Subsequently, the encoder is programmed to code each frame in INTER-coded format, unless one of the following conditions is met: 1) it is judged that the current frame being coded is so dissimilar from the reference frame used in its prediction that excessive prediction error information is produced; 2) a predefined INTRA frame repetition interval has expired; or 3) feedback is received from a receiving terminal indicating a request for a frame to be provided in INTRA-coded format.

The occurrence of condition 1) is detected by monitoring the output of the combiner 316. The combiner 316 forms a difference between the current macroblock of the frame

5

being coded and its prediction, produced in the motion compensated prediction block **350**. If a measure of this difference (for example a sum of absolute differences of pixel values) exceeds a predetermined threshold, the combiner **316** informs the control manager **360** via a control line **319** and the control manager **360** operates the switches **302** and **314** via control line **313** so as to switch the encoder **300** into INTRA-coding mode. Occurrence of condition 2) is monitored by means of a timer or frame counter implemented in the control manager **360**, in such a way that if the timer expires, or the frame counter reaches a predetermined number of frames, the control manager **360** operates the switches **302** and **314** via control line **313** to switch the encoder into INTRA-coding mode. Condition 3) is triggered if the control manager **360** receives a feedback signal from, for example, a receiving terminal, via control line **321** indicating that an INTRA frame refresh is required by the receiving terminal. Such a condition may arise, for example, if a previously transmitted frame is badly corrupted by interference during its transmission, rendering it impossible to decode at the receiver. In this situation, the receiving decoder issues a request for the next frame to be encoded in INTRA-coded format, thus re-initialising the coding sequence.

Operation of the encoder **300** in INTRA-coding mode will now be described. In INTRA-coding mode, the control manager **360** operates the switch **302** to accept video input from input line **318**. The video signal input is received macroblock by macroblock from input **301** via the input line **318**. As they are received, the blocks of luminance and chrominance values which make up the macroblock are passed to the DCT transformation block **304**, which performs a 2-dimensional discrete cosine transform on each block of values, producing a 2-dimensional array of DCT coefficients for each block. In a situation such as that described earlier, where each macroblock comprises four 8x8 pixel blocks of luminance values and two spatially corresponding 8x8 pixel blocks of chrominance values, DCT transformation block **304** produces an 8x8 array of coefficient values for each block.

The DCT coefficients for each block are passed to the quantizer **306**, where they are quantized using a quantization parameter QP. Selection of the quantization parameter QP is controlled by the control manager **360** via control line **315**. Quantization introduces a loss of information, as the quantized coefficients have a lower numerical precision than the coefficients originally generated by the DCT transformation block **304**. This provides a further mechanism by which the amount of data required to represent each image of the video sequence can be reduced. However, unlike the DCT transformation, which is essentially lossless, the loss of information introduced by quantization causes an irreversible degradation in image quality. The greater the degree of quantization applied to the DCT coefficients, the greater the loss of image quality.

The quantized DCT coefficients for each block are passed from the quantizer **306** to the video multiplex coder **370**, as indicated by line **325** in FIG. 1. The video multiplex coder **370** orders the transform coefficients for each block using a zigzag scanning procedure. This operation converts the two-dimensional array of quantized transform coefficients into a one-dimensional array. Typical zigzag scanning orders, such as that shown in FIG. 3, order the coefficients approximately in ascending order of spatial frequency. This also tends to order the coefficients according to their values, such that coefficients positioned earlier in the one-dimensional array are more likely to have larger absolute

6

values than coefficients positioned later in the array. This is because lower spatial frequencies tend to have higher amplitudes within the image blocks. Consequently, the last values in the one-dimensional array of quantized transform coefficients are commonly zeros.

Run-Level Coding of DCT Transform Coefficients

Typically, the video multiplex coder **370** represents each non-zero quantized coefficient in the one dimensional array by two values, referred to as level and run. Level is the value of the quantized coefficient and run is the number of consecutive zero-valued coefficients preceding the coefficient in question. The run and level values for a given coefficient are ordered such that the level value precedes the associated run value. A level value equal to zero is used to indicate that there are no more non-zero coefficient values in the block. This 0-level value is referred to as an EOB (end-of-block) symbol.

Entropy Coding

The run and level values are further compressed in the video multiplex coder **370** using entropy coding. Entropy coding is a lossless operation, which exploits the fact that symbols within a data set to be coded generally have different probabilities of occurrence. Therefore, instead of using a fixed number of bits to represent each symbol, a variable number of bits is assigned such that symbols which are more likely to occur are represented by code-words having fewer bits. For this reason, entropy coding is often referred to as Variable Length Coding (VLC). Since certain values of levels and runs are more likely than other values to occur, entropy coding techniques can be used effectively to reduce the number of bits required to represent the run and level values. A number of different methods can be used to implement entropy coding. For example, entropy coding of the run and level parameters may be implemented by means of look-up tables which define the mapping between each possible symbol in the data set to be coded and its corresponding variable length code. Such look-up tables are often defined by statistical analysis of training material comprising symbols identical to those to be coded and having similar statistical properties. An alternative technique, known as arithmetic coding, can also be used to convert the run and level values into variable length code-words. In arithmetic coding a group of symbols, for example the run and level values for a block of quantized transform coefficients, are coded as a floating point decimal number.

Once the run and level values have been entropy coded using an appropriate method, the video multiplex coder further combines them with control information, also entropy coded using a variable length coding method appropriate for the kind of information in question, to form a single compressed bit-stream of coded image information **335**.

A locally decoded version of the macroblock is also formed in the encoder **300**. This is done by passing the quantized transform coefficients for each block, output by quantizer **306**, through inverse quantizer **308** and applying an inverse DCT transform in inverse transformation block **310**. In this way a reconstructed array of pixel values is constructed for each block of the macroblock. The resulting decoded image data is input to combiner **312**. In INTRA-coding mode, switch **314** is set so that the input to the combiner **312** via switch **314** is zero. In this way, the operation performed by combiner **312** is equivalent to passing the decoded image data unaltered.

As subsequent macroblocks of the current frame are received and undergo the previously described encoding and decoding steps in blocks **304**, **306**, **308**, **310** and **312**, a

7

decoded version of the INTRA-coded frame is built up in frame store **320**. When the last macroblock of the current frame has been INTRA-coded and subsequently decoded, the frame store **320** contains a completely decoded frame, available for use as a prediction reference frame in coding a

subsequently received video frame in INTER-coded format. Operation of the encoder **300** in INTER-coding mode will now be described. In INTER-coding mode, the control manager **360** operates switch **302** to receive its input from line **317**, which comprises the output of combiner **316**. The combiner **316** receives the video input signal macroblock by macroblock from input **301**. As combiner **316** receives the blocks of luminance and chrominance values which make up the macroblock, it forms corresponding blocks of prediction error information. The prediction error information represents the difference between the block in question and its prediction, produced in the motion compensated prediction block **350**. More specifically, the prediction error information for each block of the macroblock comprises a two-dimensional array of values, each of which represents the difference between a pixel value in the block of luminance or chrominance information being coded and a decoded pixel value obtained by forming a motion-compensated prediction for the block, according to the procedure described below. Thus, in a situation where each macroblock comprises four 8×8 pixel blocks of luminance values and two spatially corresponding 8×8 pixel blocks of chrominance values, the prediction error information for the macroblock similarly comprises four 8×8 blocks of luminance prediction error values and two spatially corresponding 8×8 blocks of chrominance prediction error values.

The prediction error information for each block of the macroblock is passed to DCT transformation block **304**, which performs a two-dimensional discrete cosine transform on each block of prediction error values to produce a two-dimensional array of DCT transform coefficients for each block. Thus, in a situation where the prediction error information for each macroblock comprises four 8×8 blocks of luminance prediction error values and two spatially corresponding 8×8 blocks of chrominance prediction error values, DCT transformation block **304** produces an 8×8 array of transform coefficient values for each prediction error block. The transform coefficients for each prediction error block are passed to quantizer **306** where they are quantized using a quantization parameter QP, in a manner analogous to that described above in connection with operation of the encoder in INTRA-coding mode. Again, selection of the quantization parameter QP is controlled by the control manager **360** via control line **315**.

The quantized DCT coefficients representing the prediction error information for each block of the macroblock are passed from quantizer **306** to video multiplex coder **370**, as indicated by line **325** in FIG. 1. As in INTRA-coding mode, the video multiplex coder **370** orders the transform coefficients for each prediction error block using the previously described zigzag scanning procedure (see FIG. 3) and then represents each non-zero quantized coefficient as a level and a run value. It further compresses the run and level values using entropy coding, in a manner analogous to that described above in connection with INTRA-coding mode. Video multiplex coder **370** also receives motion vector information (described in the following) from motion field coding block **340** via line **326** and control information from control manager **360**. It entropy codes the motion vector information and forms a single bit-stream of coded image information, **335** comprising the entropy coded motion vector, prediction error and control information.

8

The quantized DCT coefficients representing the prediction error information for each block of the macroblock are also passed from quantizer **306** to inverse quantizer **308**. Here they are inverse quantized and the resulting blocks of inverse quantized DCT coefficients are applied to inverse DCT transform block **310**, where they undergo inverse DCT transformation to produce locally decoded blocks of prediction error values. The locally decoded blocks of prediction error values are then input to combiner **312**. In INTER-coding mode, switch **314** is set so that the combiner **312** also receives predicted pixel values for each block of the macroblock, generated by motion-compensated prediction block **350**. The combiner **312** combines each of the locally decoded blocks of prediction error values with a corresponding block of predicted pixel values to produce reconstructed image blocks and stores them in frame store **320**.

As subsequent macroblocks of the video signal are received from the video source and undergo the previously described encoding and decoding steps in blocks **304**, **306**, **308**, **310**, **312**, a decoded version of the INTER-coded frame is built up in frame store **320**. When the last macroblock of the frame has been INTER-coded and subsequently decoded, the frame store **320** contains a completely decoded frame, available for use as a prediction reference frame in encoding a subsequently received video frame in INTER-coded format.

Formation of a prediction for a macroblock of the current frame will now be described. Any frame encoded in INTER-coded format requires a reference frame for motion-compensated prediction. This means, necessarily, that when encoding a video sequence, the first frame to be encoded, whether it is the first frame in the sequence, or some other frame, must be encoded in INTRA-coded format. This, in turn, means that when the video encoder **300** is switched into INTER-coding mode by control manager **360**, a complete reference frame, formed by locally decoding a previously encoded frame, is already available in the frame store **320** of the encoder. In general, the reference frame is formed by locally decoding either an INTRA-coded frame or an INTER-coded frame.

The first step in forming a prediction for a macroblock of the current frame is performed by motion estimation block **330**. The motion estimation block **330** receives the blocks of luminance and chrominance values which make up the current macroblock of the frame to be coded via line **328**. It then performs a block matching operation in order to identify a region in the reference frame which corresponds substantially with the current macroblock. In order to perform the block matching operation, motion field estimation block accesses reference frame data stored in frame store **320** via line **327**. More specifically, motion estimation block **330** performs block-matching by calculating difference values (e.g. sums of absolute differences) representing the difference in pixel values between the macroblock under examination and candidate best-matching regions of pixels from a reference frame stored in the frame store **320**. A difference value is produced for candidate regions at all possible offsets within a predefined search region of the reference frame and motion estimation block **330** determines the smallest calculated difference value. The offset between the macroblock in the current frame and the candidate block of pixel values in the reference frame that yields the smallest difference value defines the motion vector for the macroblock in question.

Once the motion estimation block **330** has produced a motion vector for the macroblock, it outputs the motion vector to the motion field coding block **340**. The motion field

coding block **340** approximates the motion vector received from motion estimation block **330** using a motion model comprising a set of basis functions and motion coefficients. More specifically, the motion field coding block **340** represents the motion vector as a set of motion coefficient values which, when multiplied by the basis functions, form an approximation of the motion vector. Typically, a translational motion model having only two motion coefficients and basis functions is used.

The motion coefficients are passed from motion field coding block **340** to motion compensated prediction block **350**. Motion compensated prediction block **350** also receives the best-matching candidate region of pixel values identified by motion estimation block **330** from frame store **320**. Using the approximate representation of the motion vector generated by motion field coding block **340** and the pixel values of the best-matching candidate region of pixels from the reference frame, motion compensated prediction block **350** generates an array of predicted pixel values for each block of the macroblock. Each block of predicted pixel values is passed to combiner **316** where the predicted pixel values are subtracted from the actual (input) pixel values in the corresponding block of the current macroblock. In this way a set of prediction error blocks for the macroblock is obtained.

Operation of the video decoder **400**, shown in FIG. 2 will now be described. The decoder **400** comprises a video multiplex decoder **470**, which receives an encoded video bit-stream **335** from the encoder **300** and demultiplexes it into its constituent parts, an inverse quantizer **410**, an inverse DCT transformer **420**, a motion compensated prediction block **440**, a frame store **450**, a combiner **430**, a control manager **460**, and an output **480**.

The control manager **460** controls the operation of the decoder **400** in response to whether an INTRA- or an INTER-coded frame is being decoded. An INTRA/INTER trigger control signal, which causes the decoder to switch between decoding modes is derived, for example, from picture type information provided in a header portion of each compressed video frame received from the encoder. The INTRA/INTER trigger control signal is extracted from the encoded video bit-stream by the video multiplex decoder **470** and is passed to control manager **460** via control line.

Decoding of an INTRA-coded frame is performed on a macroblock-by-macroblock basis, each macroblock being decoded substantially as soon as encoded information relating to it is identified in the received video bit-stream **335**. The video multiplex decoder **470** first separates the encoded information for the blocks of the macroblock from possible control information relating to the macroblock in question. The encoded information for each block of an INTRA-coded macroblock comprises variable length code-words. These code-words represent the entropy coded level and run values for the non-zero quantized DCT coefficients of the block. The video multiplex decoder **470** decodes the variable length code-words using a variable length decoding method corresponding to the encoding method used in the encoder **300** and thereby recovers the level and run values. It then reconstructs the array of quantized transform coefficient values for each block of the macroblock and passes them to inverse quantizer **410**. Any control information relating to the macroblock is also decoded in the video multiplex decoder using an appropriate variable length decoding method and is passed to control manager **460**. In particular, information relating to the level of quantization applied to the transform coefficients is extracted from the encoded bit-stream by video multiplex decoder **470** and is provided to control manager **460** via control line **324**. The control

manager, in turn, conveys this information to inverse quantizer **420** via control line. Inverse quantizer **410** inverse quantizes the quantized DCT coefficients for each block of the macroblock according to the control information and provides the now inverse quantized DCT coefficients to inverse DCT transformer **420**.

Inverse DCT transformer **420** performs an inverse DCT transform on the inverse quantized DCT coefficients for each block of the macroblock to form a decoded block of image information comprising reconstructed pixel values. As motion-compensated prediction is not used in the encoding/decoding of INTRA-coded macroblocks, control manager **460** controls combiner **430** in such a way as to prevent any reference information being used in the decoding of the INTRA-coded macroblock. The reconstructed pixel values for each block of the macroblock are passed to the video output **480** of the decoder where, for example, they can be provided to a display device (not shown). The reconstructed pixel values for each block of the macroblock are also stored in frame store **450**. As subsequent macroblocks of the INTRA-coded frame are decoded and stored, a decoded frame is progressively assembled in the frame store **450** and thus becomes available for use as a reference frame for motion compensated prediction in connection with the decoding of subsequently received INTER-coded frames.

INTER-coded frames are also decoded macroblock by macroblock, each INTER-coded macroblock being decoded substantially as soon as encoded information relating to it is identified in the received bit-stream. The video multiplex decoder **470** separates the encoded prediction error information for each block of the INTER-coded macroblock from encoded motion vector information and possible control information relating to the macroblock in question. As explained in the foregoing, the encoded prediction error information for each block of the macroblock comprises variable length codewords which represent the entropy coded level and run values for the non-zero quantized transform coefficients for the prediction error block in question. The video multiplex decoder **470** decodes the variable length code-words using a variable length decoding method corresponding to the encoding method used in the encoder **300** and thereby recovers the level and run values. It then reconstructs an array of quantized transform coefficient values for each prediction error block and passes them to inverse quantizer **410**. Control information relating to the INTER-coded macroblock is also decoded in the video multiplex decoder using an appropriate variable length decoding method and is passed to control manager **460**. Information relating to the level of quantization applied to the transform coefficients of the prediction error blocks is extracted from the encoded bit-stream and provided to control manager **460** via control line **324**. The control manager, in turn, conveys this information to inverse quantizer **410** via control line. Inverse quantizer **410** inverse quantizes the quantized DCT coefficients representing the prediction error information for each block of the macroblock according to the control information and provides the now inverse quantized DCT coefficients to inverse DCT transformer **420**. The inverse quantized DCT coefficients representing the prediction error information for each block are then inverse transformed in the inverse DCT transformer **420** to yield an array of reconstructed prediction error values for each block of the macroblock.

The encoded motion vector information associated with the macroblock is extracted from the encoded video bit-stream **335** by video multiplex decoder **470** and is decoded using an appropriate variable length decoding method. The

decoded motion vector information thus obtained is passed via data line 326 to motion compensated prediction block 440, which reconstructs a motion vector for the macroblock using the same motion model as that used to encode the INTER-coded macroblock in encoder 300. The reconstructed motion vector approximates the motion vector originally determined by motion estimation block 330 of the encoder. The motion compensated prediction block 440 of the decoder uses the reconstructed motion vector to identify the location of a region of reconstructed pixels in a prediction reference frame stored in frame store 450. The reference frame may be, for example, a previously decoded INTRA-coded frame, or a previously decoded INTER-coded frame. In either case, the region of pixels indicated by the reconstructed motion vector is used to form a prediction for the macroblock in question. More specifically, the motion compensated prediction block 440 forms an array of pixel values for each block of the macroblock by copying corresponding pixel values from the region of pixels identified in the reference frame. The prediction, that is the blocks of pixel values derived from the reference frame, are passed from motion compensated prediction block 440 to combiner 430 where they are combined with the decoded prediction error information. In practice, the pixel values of each predicted block are added to corresponding reconstructed prediction error values output by inverse DCT transformer 420. In this way an array of reconstructed pixel values for each block of the macroblock is obtained. The reconstructed pixel values are passed to the video output 480 of the decoder and are also stored in frame store 450. As subsequent macroblocks of the INTER-coded frame are decoded and stored, a decoded frame is progressively assembled in the frame store 450 and thus becomes available for use as a reference frame for motion-compensated prediction of other INTER-coded frames.

H.26L Video Coding Standard

ITU-T recommendation H.26L is the latest in a family of video coding standards developed by the International Telecommunications Union. It is intended in particular for video coding at very low bit rates, typically below 64 kbits/s, which makes it especially suitable for the coding of digital video for transmission via radio communication networks or any fixed line communication network in which optimal use of available bandwidth is a priority. The video encoding system defined by ITU-T H.26L is a hybrid video coding system, which operates according to the general principles described above in connection with the generic video encoder 300 and decoder 400 illustrated in FIGS. 1 and 2. In particular, a video encoding system implemented according to H.26L employs a combination of block-based transform coding and motion-compensated prediction to reduce the spatial and temporal redundancy within video sequences.

The latest version of the H.26L recommendation, known as Test Model 8 (TML8) and described in "H.26L Test Model Long Term Number 8 (TML-8) draft0" (ITU-T Telecommunications Standardization Section, Study Group 16, Video Coding Experts Group), specifies two alternative entropy coding modes. In the first (default) mode a so-called Universal Variable Length Coding (UVLC) method is used to encode all syntax elements. The UVLC coding mode is a look-up table method in which the same set of variable length code-words is used to represent all the different kinds of information produced by the video encoder, regardless of the type of information in question. The alternative entropy coding method, specified for use in the so-called high complexity profile of H.26L, is a technique known as Context-based Adaptive Binary Arithmetic Coding (CABAC). This is a form of binary arithmetic coding which

continually adapts to the statistical properties of the information being coded and is known in the art to be one of the most efficient forms of entropy coding (see H. Witten, R. M. Neal, and J. G. Cleary, "Arithmetic coding for data compression," *Commun. ACM*, vol. 30, pp. 520-540, June 1987).

Because UVLC entropy coding uses the same set of variable length code-words to represent all types of information produced by the video encoder, in general the statistical properties of the code-words do not match optimally with the characteristics of the information to be encoded. For example, the frequency of occurrence of particular run and level values used to represent the quantized DCT coefficients for an INTRA-coded image block is likely to be different from the occurrence of values in control information relating to quantization parameter values. The CABAC entropy coding method was introduced into the H.26L recommendation in order to overcome the inherently sub-optimal nature of the UVLC entropy coding method. As explained earlier in the text, arithmetic coding represents a group of symbols to be coded with a single variable length code (a floating-point number). This provides particular advantages compared with entropy coding methods, which encode each symbol independently. Specifically, entropy coding methods which encode each symbol independently require at least one bit to represent each symbol. Because arithmetic coding represents groups of symbols with a single code-word, it is possible to achieve data compression rates of less than one bit per symbol. Thus the CABAC method provided in H.26L also provides the possibility of improved data compression. Furthermore, because it is an adaptive method, it is also able to take into account changes in the statistical characteristics of the information being coded, ensuring that data compression performance is maintained even if the nature of the data being encoded changes to some extent.

Context-Based Arithmetic Coding

As explained above, CABAC arithmetic coding is an entropy coding method, which is able to adapt to changing statistics of the information to be encoded. In this way it is capable of providing improved compression efficiency compared with entropy coding techniques which assume fixed statistical properties. FIG. 4 illustrates an exemplary context-based binary arithmetic encoder 700. CABAC is a binary arithmetic coding method and thus data symbols to be coded which have non-binary values are first converted to binary values ('binarized') in binary mapping block 710. The binarization process involves mapping a symbol to be coded to a sequence of bins, each of which has a corresponding bin number and can be assigned a value of either 0 or 1. An example of such a mapping is given below in Table 1. In principle other binarization schemes can be envisaged.

TABLE 1

value	Bin Sequence							
0	1							
1	0	1						
2	0	0	1					
3	0	0	0	1				
4	0	0	0	0	1			
5	0	0	0	0	0	1		
6	0	0	0	0	0	0	1	
...
bin_nr.	1	2	3	4	5	6	7	.

In the CABAC method each of the bins is assigned to a so-called 'context' (hence the name context-based arithmetic coding). A context can be thought of as grouping together

bins, which have similar statistical characteristics. In other words, each bin assigned to a particular context is assumed to have a similar probability of containing the value 1 or 0 as the other bins belonging to that context. In this way, the probability estimates used to generate code-words in the arithmetic coder are defined for each context rather than for each possible bin to be encoded. Each context is defined according to a 'context model', established in advance and based on information about the statistical characteristics of the data symbols (and thus the bins) to be encoded. Generally, the data compression ratio achieved by a binary arithmetic encoder is enhanced if the difference between the probability of occurrence of a 0 and probability of occurrence of a 1 is maximised. In a similar way, the performance of a context-based arithmetic coding also depends on the choice of context model. This means that, in general, context models should be chosen so as to maximise the difference between the probability of occurrence of 0's and 1's for the bins assigned to each context.

In the exemplary context-based arithmetic coder illustrated in FIG. 4, once a symbol to be coded has been binarized in binary mapping block 710 it is assigned to a corresponding context in context assignment block 720. The value assigned to the corresponding bin (i.e., 1 or 0) is then passed to the arithmetic coder 730. The coding engine 750 of arithmetic coder 730 then encodes the bin value using a probability estimate for the context to which the bin is assigned. The performance, that is the data compression ratio achieved by the arithmetic encoder, depends on the accuracy of the probability estimates. In principle, the estimates may be fixed or adaptive. If fixed probability estimates are used, the probability estimates for each context are assigned to predefined values and remain unchanged during the encoding process. Fixed probability estimates are typically obtained in advance by analysing training material having statistical properties similar to those of the actual data to be encoded. If adaptive probability estimates are used, fixed values are used to initialise the probability estimates for each context and the probabilities are then updated throughout the encoding process based on the actual statistical properties of the data (bins) encoded so far. Adaptive probability estimates generally perform better since they can adjust to the material being encoded.

The exemplary context-based arithmetic coder illustrated in FIG. 4 employs adaptive probability estimates and comprises a probability estimation block 740 where updated probability estimates are calculated. The probability estimates for each context are updated by keeping a record of the number of occurrences of 1 and 0 for each of the bins assigned to each context. For example, if the bins assigned to an arbitrary context k have been assigned the value 0 m times and the value 1 n times, then the probability estimate for 1 in context k is $n/(n(m+1))$ and the probability estimate for 0 is $(m+1)/(n(m+1))$.

FIG. 5 illustrates a context-based arithmetic decoder 800 corresponding to the encoder described in connection with FIG. 4. A bit-stream representing arithmetic coded data symbols is received by the context-based arithmetic decoder at input 810. Initially, based on the previously decoded symbols, a context is calculated in a context assignment block 850 and the probability estimates of the bin values are updated. Context assignment, as carried out in the context assignment block 850, and calculation of probability estimates, as carried out in the probability estimation block 830, are done in the same manner as the encoder. The received bits are then fed into an arithmetic decoding engine 840 of the arithmetic decoder 820, where they are converted

to decoded bin values, using the calculated context and the current probability estimates of the bin values. Decoded bins are mapped to the values of the runs and levels in a bin-to-value mapping block 860.

CABAC Method as Used in H.26L

The details of the CABAC arithmetic coding method adopted for use in the high complexity profile of ITU-T recommendation H.26L will now be described in detail. According to H.26L TML8, the contexts for run and level values depend on the type of block being encoded and the bin number of the binarized level or run value. Different block types are defined according to the scanning mode (single/double) used to order the coefficient values, the component type (luminance/chrominance, AC/DC), or the coding mode (INTER/INTRA). However, for a given block type, the context depends only on the bin number. More specifically, according to H.26L TML8 four contexts are defined for level encoding. The first one is for the first bin, the second is for the second bin, while the third context is for the rest of the bins representing the magnitude of the level. The remaining context is used for the sign of the level. A similar approach is used to assign run values to contexts. For runs there are three contexts, the first one for the first bin, the second for the second bin and the third for all remaining bins. As run values are always equal to or greater than zero, there is no need for an additional context to represent sign information. Thus, for a block of a given type, the assignment of bins to contexts for transform coefficient bins (for both level and run encoding) can be summarised as follows:

```

if (bin_nr > MAX_BIN_VAL)
    bin_nr = MAX_BIN_VAL;
end
context = bin_nr

```

where `bin_nr` is the bin number and `context` is the context number. According to H.26L TML8, the value of `MAX_BIN_VAL` is set equal to 3, but in principle another `MAX_BIN_VAL` could be used instead.

A run-level pair is encoded as follows: The runs and levels are first classified according to block/coefficient type: scanning mode, coefficient type (DC/AC), and coding mode (INTER/INTRA or 16x16 INTRA). The levels and runs are then binarized by mapping them onto a sequence of bins and each bin is assigned to a context based on its bin number.

FIGS. 6a–6d illustrate this process in detail with reference to an exemplary 4x4 array of quantized DCT coefficients. It also demonstrates the adaptive nature of the CABAC method, by illustrating the way in which the statistical properties of run and level values for quantized DCT coefficients are tracked. The two-dimensional array of quantized DCT coefficient values is first zigzag scanned to produce a one-dimensional array of values, as indicated in FIG. 6a. The non-zero coefficient values in the one-dimensional array are then represented as pairs of run and level values. As previously explained, each level value represents the value of a non-zero quantized DCT coefficient, while the associated run value corresponds to the number of zero-valued coefficients preceding the coefficient in question. The run-level pairs derived from the exemplary array of quantized DCT coefficients are presented in FIG. 6b. In each pair the level value precedes the associated run value and a level value equal to zero is used as an end-of-block symbol to indicate that there are no more non-zero coefficient values in the block.

Next, each run and level value is converted into a binary value. According to H.26L TML8, the binarization scheme

15

used to convert the run and level values for quantized DCT transform coefficient values is identical to that shown above in Table 1. FIG. 6c shows the result of applying the binarization scheme presented in Table 1 to the run and level values in the exemplary array. FIG. 6c also shows the assignment of bins to contexts according to H.26L. As described above, only three contexts are used to describe the magnitudes of the run and level values. The first context corresponds to bin 1, the second to bin 2, while the third context comprises all the remaining bins. In FIG. 6c, the contexts are delineated by bold horizontal lines. By examining FIG. 6c it can be seen that the majority of level values are mapped to bins which are assigned to context 3, while the majority of run values are mapped to bins which are assigned to context 1.

The probability estimates for each assigned context are updated after the encoding of the bins. Probability estimates for the run and level contexts are updated independently. As previously described, the probability estimate for a given context represents the statistical characteristics of the bins assigned to the context in question. More specifically, the probability estimate describes the likelihood of a bin assigned to the context containing a 1 or a 0. FIG. 6d describes, in an exemplary manner, the way in which the probability estimates are updated for runs and levels. The figure illustrates the probability of a bin assigned to a given run or level context containing a 1 or a 0 before and after the runs and levels representing the 4x4 block of quantized DCT coefficients shown in FIG. 6a are binarized and assigned to contexts and encoded in the arithmetic encoder. FIG. 6d takes the form of a table, which records the occurrence of 1's and 0's in the bins assigned to each context. Thus, the probability estimate for a given context is given by:

probability of 0=no. of 0's/(no. of 0's+no. of 1's)

probability of 1=no. of 1's/(no. of 0's+no. of 1's)

In the figure it is assumed that the 4x4 block of quantized DCT coefficients shown in FIG. 6a is the first such block to be processed. This means that there are no previous occurrences of 1's and 0's to record in the table. To overcome this problem it is assumed that before the block is processed, each context has an equal probability of containing a 1 or a 0. This is indicated by entering identical values in the columns that record the occurrence of 0's and 1's. In FIG. 6d, 1's are used to initialize the probability estimate. Alternatively, a probability estimate derived from analysis of training data could be used to initialize the probability estimates for each context. The probability estimates are then updated by counting the number of 1's and 0's which occur in the bins of each context as the run and level values for the block of quantized DCT transform coefficients are binarized and assigned to contexts. The right-hand column of FIG. 6d shows the situation after processing the 4x4 block of quantized DCT shown in FIG. 6a.

Although the CABAC arithmetic encoding method adopted in the high complexity profile of ITU-T recommendation H.26L TML8 provides an improvement in data compression compared with the UVLC entropy coding method, it is still not optimal with regard to coding efficiency. It is therefore an object of the invention to provide a method and system for context-based arithmetic coding, wherein coding efficiency is further improved.

SUMMARY OF THE INVENTION

The present invention is based on the realization that when coding a given data symbol using context-based arithmetic coding, an improvement in coding efficiency can be achieved by using context models which take into

16

account the contexts to which other data symbols are assigned. With specific reference to the CABAC method used in the high complexity profile of H.26L TML8, the inventors of the present invention have determined that certain relationships exist between the run and level values associated with DCT transform coefficients. They have further determined that these relationships can be used to construct improved context models which enable the CABAC method to operate with improved coding efficiency when applied to the run and level values. In particular, the inventors have determined that consecutive level values exhibit a significant similarity. More specifically, within a given block of transform coefficients, the level of a coefficient to be encoded has, in general, a magnitude substantially similar to the level of the previously encoded coefficient. The inventors have also determined an inverse relationship between the level and run values. In particular, larger level values are more likely to be preceded by smaller run values. The converse is also true, namely smaller level values are likely to be preceded by larger runs. Consequently, the present invention proposes the creation of new context models for the coding of DCT transform coefficients, which take into account these relationships between level and run values.

In a first such context model, intended for implementation in a context-based arithmetic encoder, the context assigned to the bins of a binarized coefficient level value depends on the previously encoded coefficient level. In a second such context model, intended for implementation in a context-based arithmetic decoder, the context assigned to the bins of a binarized coefficient level value depends on the previously decoded coefficient level. In a third context model, implemented in either a context-based arithmetic encoder or a context-based arithmetic decoder, the context assigned to the bins of a binarized coefficient run value depends on the coefficient's level value.

The inventors have also determined that certain similarities exist between the transform coefficient values associated with different image blocks. These similarities are greater between image blocks which reside close to each other and tend to be strongest between immediately neighbouring image blocks. More specifically, the number N_c of non-zero transform coefficient values representing a particular image block tends to be similar to the number of non-zero transform coefficient values in an image block close to, or neighbouring, the image block in question. Thus, the present invention further introduces the concept of providing an indication of the number of non-zero transform coefficients for a transform coded image block and encoding this value using entropy coding. Furthermore, if context-based arithmetic coding is used to encode the N_c value, the inventors have determined that it is advantageous to assign the N_c value of a block to a context by taking into account the context assigned to the N_c value for at least one other transform coded image block. In this way the similarity between N_c values between image blocks which reside close to each other can be taken advantage of in the context-based arithmetic coding procedure. According to ITU-T recommendation H.26L TML8, the number of non-zero transform coefficients in an image block is not encoded. Instead, and as previously explained, an end-of-block (EOB) indication is provided. The EOB indication signals that the last run-level pair corresponding to a non-zero coefficient has been encoded. The inventors have determined that the proposed method, in which an explicit indication of the number of non-zero coefficients in a block is provided and coded using context-based arithmetic coding leads to an increase in the

coding efficiency compared with the method of providing an EOB indication as currently employed in H.26L TML8.

Although the motivation behind the present invention and its basic concepts have been presented in the context of video encoding/decoding and more specifically with respect to H.26L TML8, it should be appreciated that invention may be applied in other video coding systems and also to still image coding. In principle the invention can be applied in any image coding system in which block-based transform coding and context-based arithmetic coding are used.

According to a first aspect of the present invention there is provided a method of image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixel values to produce a corresponding block of transform coefficient values. The block of transform coefficient values is scanned in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order wherein the coefficient values in the scanned array are represented by a plurality of number pairs, each having a first number indicative of a non-zero coefficient value and a second number indicative of a number of consecutive zero coefficient values preceding the non-zero coefficient value, and wherein the first and the second number are each assigned to one of a plurality of contexts indicative of the number pairs. The method comprises the step of assigning a further value to a context based on a third number indicative of a preceding value.

Preferably, the further value is the first number in one of the number and the preceding value is the first number of a preceding number pair.

Preferably, the step of assigning the first number in one of the number pairs to a context based on a third number indicative of the first number of a preceding number pair further takes into account the context to which the first number of the number pair is assigned.

Advantageously, the first number is equal to the magnitude of a non-zero coefficient value.

Preferably, the contexts are contexts of a context-based arithmetic coder.

Even more preferably, the contexts are contexts of a context-based binary arithmetic coder.

Advantageously, each of the first, second and third numbers is mapped to a set of bins, each of the bins having an associated bin number and being capable of taking one of either a first value or a second value.

Preferably, each of the first, second and third numbers is mapped to one of the set of bins, mapping of a number to a given one of the set of bins being indicated by assigning the value of the bin to the first value.

Preferably the first value is 1 and the second value is 0.

Preferably each of the set of bins is assigned to a context.

Advantageously, the step of assigning the first number in one of the number pairs to a context based on a third number indicative of the first number of a preceding number pair further taking into account the context to which the first number in the preceding number pair is assigned is implemented by examining the bin number of the bin to which the first number of the preceding number pair is mapped.

Advantageously, the method further comprises maintaining a probability estimate describing the statistical properties of each context.

Preferably, for each context, the probability estimate is indicative of the statistical likelihood of a number having a predetermined value being assigned to the context.

Preferably, for each context, the probability estimate is maintained by keeping a record of occurrences of the first value and the second value in the bins assigned to the context in question.

According to a second aspect of the present invention there is provided a method of image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixel values to produce a corresponding block of transform coefficient values. The block of transform coefficient values is scanned in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order wherein the coefficient values in the scanned array are represented by (converted into) a plurality of number pairs, each having a first number indicative of a non-zero coefficient value and a second number indicative of a number of consecutive zero coefficient values preceding the non-zero coefficient value, and wherein the first and the second number are each assigned to one of a plurality of contexts indicative of the number pairs. The method comprises the step of assigning the second number in one of the number pairs to a context based on the first number of the number pair.

Preferably, the step of assigning the second number in one of the number pairs to a context based on the first number of the number pair further takes into account the context to which the second number in the one of the number pairs is assigned.

Advantageously, the first number is equal to the magnitude of a non-zero coefficient value.

Preferably, the contexts are contexts of a context-based arithmetic coder.

Even more preferably, the contexts are contexts of a context-based binary arithmetic coder.

Advantageously, each of the first and second numbers is mapped to a set of bins, each of the bins having an associated bin number and being capable of taking one of either a first value or a second value.

Preferably, each of the first and second numbers is mapped to one of the set of bins, mapping of a number to a given one of the set of bins being indicated by assigning the value of the bin to the first value.

Preferably the first value is 1 and the second value is 0.

Preferably each of the set of bins is assigned to a context.

Advantageously, the step of assigning the second number in one of the number pairs to a context based on the first number of the number pair further taking into account the context to which the second number in the one of the number pairs is assigned is implemented by examining the bin number of the bin to which the second number is mapped.

Advantageously, the method further comprises maintaining a probability estimate describing the statistical properties of each context.

Preferably, for each context, the probability estimate is indicative of the statistical likelihood of a number having a predetermined value being assigned to the context.

Preferably, for each context, the probability estimate is maintained by keeping a record of occurrences of the first value and the second value in the bins assigned to the context in question.

Preferably, the methods according to the first and the second aspect of the invention are both applied to a block of transform coefficient values.

According to a third aspect of the present invention there is provided a system for image coding, wherein an image is

divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixels to produce a corresponding block of transform coefficient values. The block of transform coefficient values is scanned in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order wherein the coefficient values in the scanned array are represented by a plurality of number pairs, each having a first number indicative of a non-zero coefficient value and a second number indicative of a number of consecutive zero coefficient values preceding the non-zero coefficient value, and wherein the first and the second number are each assigned to one of a plurality of contexts indicative of the number pairs. The system comprises a mechanism, located in the encoder, for assigning the first number in one of the number pairs to a context based on a third number indicative of the first number of a preceding number pair.

According to a fourth aspect of the present invention there is provided a system for image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixels to produce a corresponding block of transform coefficient values. The block of transform coefficient values is scanned in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order wherein the coefficient values in the scanned array are represented by a plurality of number pairs, each having a first number indicative of a non-zero coefficient value and a second number indicative of a number of consecutive zero coefficient values preceding the non-zero coefficient value, and wherein the first and the second number are each assigned to one of a plurality of contexts indicative of the number pairs. The system comprises a mechanism, located in the encoder, for assigning the second number in one of the number pairs to a context based on the first number of the number pair.

According to a fifth aspect of the present invention there is provided a method of image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixels to produce a corresponding block of transform coefficient values. The method comprises the step of providing a number indicative of the number of non-zero coefficient values in the block of transform coefficient values and assigning the number to a context.

Advantageously, the step of assigning the number indicative of the number of non-zero transform coefficient values in the block of transform coefficient values takes into account the context to which another such number indicative of the number of non-zero transform coefficient values in another block of transform coefficient is assigned.

Advantageously, the block of transform values is scanned in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order wherein the coefficient values in the scanned array are represented by a plurality of number pairs, each having a first number indicative of a non-zero coefficient value and a second number indicative of the number of consecutive zero coefficient values preceding the non-zero coefficient value.

Preferably, an end-of-block indication, indicative of the last non-zero coefficient value in the scanned array of coefficient values is not provided.

Preferably, the first number is equal to the magnitude of a non-zero coefficient value minus 1.

Preferably, the methods according to the first, second and fifth aspects of the invention are each applied to a block of transform coefficient values.

According to a sixth aspect of the present invention there is provided a system for image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on each block of pixels to produce a corresponding block of transform coefficient values. The system comprises a mechanism, located in the encoder and responsive to the coefficient values, for providing a third number indicative of the number of non-zero coefficient values in the block of transform coefficient values and assigning the number to a context.

Advantageously, the system further comprises a mechanism for assigning the number indicative of the number of non-zero transform coefficient values in the block of transform coefficient values taking into account the context to which another such number indicative of the number of non-zero transform coefficient values in another block of transform coefficient is assigned.

According to a seventh aspect of the present invention there is provided a computer program comprising code for performing a method of image coding, in which an image is divided into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixel values to produce a corresponding block of transform coefficient values. The computer program also comprises code for scanning the block of transform coefficient values in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order wherein the coefficient values in the scanned array are represented by a plurality of number pairs, each having a first number indicative of a non-zero coefficient value and a second number indicative of a number of consecutive zero coefficient values preceding the non-zero coefficient value, and wherein the first and the second number are each assigned to one of a plurality of contexts indicative of the number pairs. The computer program also comprises code for assigning the first number in one of the number pairs to a context based on a third number indicative of the first number of a preceding number pair.

According to an eighth aspect of the present invention there is provided a computer program comprising code for performing a method of image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixel values to produce a corresponding block of transform coefficient values. The computer program also comprises code for scanning the block of transform coefficient values in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order wherein the coefficient values in the scanned array are represented by a plurality of number pairs, each having a first number indicative of a non-zero coefficient value and a second number indicative of a number of consecutive zero coefficient values preceding the non-zero coefficient value, and wherein the first and the second number are each assigned to one of a plurality of contexts indicative of the number pairs. The computer program further comprises code for assigning the second number in one of the number pairs to a context based on the first number of the number pair.

According to a ninth aspect of the present invention there is provided a computer program comprising code for per-

forming a method of image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixels to produce a corresponding block of transform coefficient values. The computer program further comprises code for providing a number indicative of the number of non-zero coefficient values in the block of transform coefficient values and assigning the number to a context.

Advantageously, the computer program further comprises code for assigning the number indicative of the number of non-zero transform coefficient values in the block of transform coefficient values taking into account the context to which another such number indicative of the number of non-zero transform coefficient values in another block of transform coefficient is assigned.

According to a tenth aspect of the invention there is provided a computer program according to the seventh, eighth and ninth aspects of the invention.

The present invention will become apparent upon reading the description taken in conjunction with FIGS. 7a to 12.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 is a block diagram illustrating the structure of an exemplary video encoder, which employs block-based transform coding and motion-compensated prediction.

FIG. 2 is a block diagram of an exemplary video decoder corresponding to the encoder of FIG. 1.

FIG. 3 is a diagrammatic representation showing an exemplary zig-zag scan.

FIG. 4 is a block diagram showing an encoder in a prior art context-based arithmetic coding scheme.

FIG. 5 is a block diagram showing a decoder in a prior art context-based arithmetic coding scheme.

FIG. 6a is a diagrammatic representation showing an exemplary two-dimensional array of quantized DCT coefficient values scanned in a zigzag manner.

FIG. 6b is a table showing the level and run values derived from the array of FIG. 6a.

FIG. 6c is a table showing the binarized level and run values resulted from the application of the binarization scheme of Table 1 to the level and run values of FIG. 6b.

FIG. 6d is a table showing a way in which the probability estimates are updated from runs and levels.

FIG. 7a is a table showing a way in which contexts are assigned to bins based on level values.

FIG. 7b is a table showing the way in which contexts are assigned to level values according to the first embodiment of the present invention.

FIG. 8a is a table showing a way in which contexts are assigned to bins based on run values.

FIG. 8b is a table showing the way in which contexts are assigned to run values according to the second embodiment of the present invention.

FIG. 9 is a block diagram illustrating an encoder in a context-based arithmetic coding scheme, according to the present invention.

FIG. 10 is a block diagram illustrating a decoder, according to the present invention.

FIG. 12 is a flowchart illustrating a method of image coding, according to another embodiment of the present invention.

BEST MODE TO CARRY OUT THE INVENTION

Embodiments of the invention will now be discussed in detail. As described above, the present invention provides a number of related mechanisms by which an improvement in the coding efficiency (data compression) of a context-based arithmetic coder, can be attained. This improvement is achieved by using context models, which take into account the contexts to which other data symbols are assigned.

The first embodiment of the invention, described in detail in section 1.1 below, relates to a context-based binary arithmetic coder suitable for use in an image coding system such as that defined by ITU-T recommendation H.26L. In this embodiment, level values generated by run-level coding the quantized transform coefficients of a transform coded block of image pixels are assigned to contexts taking into account the level of another transform coefficient belonging to the same block.

The second embodiment of the invention, described in detail in section 1.2, also relates to a context-based binary arithmetic coder for an image coding system such as that defined by ITU-T recommendation H.26L. In the second embodiment, run values produced by run-level coding the quantized DCT transform coefficients of a transform coded block of image pixels are assigned to contexts taking into account the level value of the run-level pair to which the run value belongs.

The third embodiment of the invention is described in section 1.3 and also relates to a context-based arithmetic coder for an image coding system such as that defined by ITU-T recommendation H.26L. According to the third embodiment, the number of non-zero transform coefficients N_c for a transform coded image block is determined and assigned to a context taking into account the context assigned to the N_c value for at least one other transform coded image block.

A preferred embodiment of the invention combines the functionality of the three above-mentioned embodiments.

As explained earlier in the text, the high complexity profile of ITU-T recommendation H.26L TML8 employs a form of context-based arithmetic coding known as CABAC. In a video encoder implemented according to H.26L, the CABAC method is used to encode a variety of different types of information produced by the encoder, including the transform coefficients generated by transform coding blocks of image pixels (in INTRA-coding mode) or prediction error values (in INTER-coding mode). The two-dimensional array of transform coefficients produced by transform coding a block of image pixels is scanned according to a particular scanning mode to produce a one-dimensional array. Two such scanning modes are defined in H.26L. The first is known as 'single-scanning mode' while the other is referred to as 'double-scanning mode'. Whichever scanning mode is used, scanning of the transform coefficients converts the two-dimensional array of coefficient values into a one-dimensional array in which the coefficients are ordered in a predetermined manner. The ordered transform coefficient values in the one-dimensional array are converted run and level values. The last entry in the ordered one-dimensional array is an end-of-block symbol, which according to H.26L TML8, takes the form of a level value equal to zero. This indicates that the last non-zero coefficient value in the ordered array has been converted into a run-level pair.

The run and level values are converted to binary numbers (binarized), by mapping them to a series of bins, each of which can be assigned the value 0 or 1 (see Table 1). The

binarized run and level values are then assigned to contexts, a separate set of contexts being defined for the runs and the levels. According to H.26L TML8, for a given block type, the set of contexts defined for levels depends only on the bin number to which the levels are assigned. More specifically, according to H.26L TML8 four contexts are defined for level encoding. The first one is for the first bin, the second is for the second bin, while the third context is for the rest of the bins representing the magnitude of the level. The remaining context is used for the sign of the level. For runs there are three contexts, the first one for the first bin, the second for the second bin and the third for all remaining bins. As run values are always equal to or greater than zero, there is no need for an additional context to represent sign information.

1.1. Context Model for Levels

According to the first embodiment of the present invention, when assigning a binarized level value to a context, in addition to considering the bin to which the level value itself is mapped, the level value of the preceding run-level pair is also taken into account. In this context, the term 'preceding run-level pair' means the run-level pair corresponding to the preceding coefficient in the ordered one-dimensional array of coefficient values. The following pseudo code presents an exemplary procedure for assigning a context to a level value of a run-level pair, taking into account both the bin to which the level itself is mapped and the level value of the preceding run-level pair:

```

if (bin_nr > MAX_BIN_LEVEL)
    bin_nr = MAX_BIN_LEVEL;
end
if (prev_level > MAX_LEVEL)
    prev_level = MAX_LEVEL;
end
context = (bin_nr-1)*MAX_LEVEL + prev_level

```

In expression (2) prev_level is the (magnitude of the) level value of the previous run-level pair. prev_level is initialized to zero at the beginning of each block. In a double scanning mode, prev_level is initialized at the beginning of each scan, twice per block. Parameter MAX_BIN_LEVEL provides a means of controlling the way in which the bin number to which the level value is mapped affects the assignment of a context. More specifically, and in a manner similar to the present assignment of contexts according to H.26L TML8, MAX_BIN_LEVEL effectively defines a context to which all bin numbers greater than or equal to MAX_BIN_LEVEL are assigned. In an similar fashion parameter MAX_LEVEL provides a means of controlling the way in which the level value of the previous run-level pair affects the assignment of a context. FIGS. 7a and 7b illustrate the way in which contexts are assigned to level values according to the first embodiment of the invention by applying the pseudo code of expression (2) with MAX_BIN_LEVEL=3 and MAX_LEVEL=5. In principle, any combination of MAX_BIN_LEVEL and MAX_LEVEL can be used to define a set of contexts appropriate for the statistical characteristics of the level values to be coded.

1.2. Context Model for Runs

According to the second embodiment of the invention an approach is similar to that described in section 1.1 is used to assign run values to contexts. More specifically, when assigning a binarized run value to a context, in addition to considering the bin to which the run value itself is mapped, the level of the run-level pair to which the run value belongs is also taken into account. The following pseudo code presents an exemplary procedure for assigning a context to

a run value of a run-level pair, taking into account both the bin to which the run itself is mapped and the level value of the run-level pair to which the run value belongs:

```

if (bin_nr > MAX_BIN_RUN)
    bin_nr = MAX_BIN_RUN;
end
if (level > MAX_RUNL)
    level = MAX_RUNL;
end
context = (bin_nr-1)*MAX_RUNL + level

```

In expression (3) level is the magnitude of the level value of the run-level pair. Parameter MAX_BIN_RUN provides a means of controlling the way in which the bin number to which the run value is mapped affects the assignment of a context. More specifically, and in a manner similar to the present assignment of contexts according to H.26L TML8, MAX_BIN_RUN effectively defines a context to which all bin numbers greater than or equal to MAX_BIN_RUN are assigned. In an similar fashion parameter MAX_RUNL provides a means of controlling the way in which the level value of run-level pair affects the assignment of a context. FIGS. 8a and 8b illustrates the way in which contexts are assigned to level values according to the second embodiment of the invention by applying the pseudo code of expression (3) with MAX_BIN_RUN=3 and MAX_RUNL=4. In principle, any combination of MAX_BIN_RUN and MAX_RUNL can be used to define a set of contexts appropriate for the statistical characteristics of the run values to be coded.

1.3 Contexts for Number of Non-Zero Coefficients

The third embodiment of the invention relates in particular to the way in which an ordered array of transform coefficient values is converted into run and level values and the way in which the number of run-level pairs corresponding to an array of quantized transform coefficient values is signaled. More specifically, after a block of image pixels or prediction error values has been transform coded to form a two-dimensional array of transform coefficient values and each of the coefficient values has been quantized, the number of non-zero quantized coefficient values in the array is determined. A value, referred to as N_c , is assigned to that number and is used to signal explicitly the number of non-zero coefficient values in the array. Thus, according to this embodiment of the invention, an EOB symbol, for example a level value equal to zero, is no longer required.

The quantized transform coefficients are further scanned according to a predetermined scanning order to produce an ordered one-dimensional array. Alternatively, N_c may be determined after ordering the quantized coefficient values. Each of the non-zero quantized coefficients in the ordered array is then converted into a run-level pair. According to this embodiment of the invention, the level value of the run-level pair denotes the magnitude of the value of the quantized coefficient minus 1 and the run value corresponds to the number of consecutive zero-valued quantized coefficients preceding the coefficient in question. The level values are assigned to the magnitude of the value of the quantized coefficient minus 1 because a level value equal to zero is no longer used as an end-of-block indicator. This gives rise to a saving in the amount of data (e.g. number of bits) required to represent the level information.

The level and run values are then encoded using entropy coding, as is the N_c value. In a situation where a context-based arithmetic coding method such as the CABAC technique implemented in H.26L TML8 is used, the run and

level values may be encoded according to the first and/or second embodiments of the invention, as described above. Alternatively any other appropriate context models may be used for the run and level values. Additionally a separate context model is defined for N_c . According to this embodiment of the invention, the N_c value representing the number of non-zero quantized transform coefficients in a given block is first binarized by mapping it to a series of bins, each of which has a corresponding bin number. The context for N_c is then determined on the basis of the bin number to which N_c is mapped and the N_c of at least one other image block or macroblock which has already been assigned an N_c value. The following pseudo code presents an exemplary procedure for assigning a context to an N_c value, taking into account both the bin to which the N_c itself is mapped and the preceding N_c value:

```

if (bin_nr > MAX_BIN_Nc)
    bin_nr = MAX_BIN_Nc;
end
if (prev_nc > MAX_Nc)
    prev_nc = MAX_Nc;
end
context = (bin_nr-1)*MAX_nc + prev_nc

```

In expression (4) prev_nc is the previous N_c value.

When encoded level and run values for a given block of quantized transform coefficients are transmitted from an encoder to a decoder, the entropy coded N_c value is transmitted before the encoded run and level values. At the decoder, the N_c value is decoded, followed by the run-level pairs corresponding to the quantized transform coefficient values for the block in question. The value of +1 is added to each of the magnitude of the level values as they are decoded in order to compensate for the corresponding subtraction made at the encoder.

To demonstrate the improvement in coding efficiency using the method of image coding, according to the present invention, the average bitrate difference is calculated using results from QP=28, 24, 20, 16. Table 2 shows the bitrate reduction in percentage, as compared to TML-8, where MAX_LEVEL=5 and MAX_RUN=4. All frames are encoded as I-frames in CABAC mode. As shown in Table 2, the reduction in bitrate ranges from 0.95 to 4.74%. The improvement is more pronounced when the QP values are small.

TABLE 2

In Tables 2, the names appearing on the first row of the table are pictures used in Gisle Bjontegaard "Recommended Simulation Conditions for H.26L" (VCG-M75, ITU-T Video Coding Experts Group, Austin, Tex., USA, 2-4, Apr., 2001).

Referring now to FIG. 9, an encoder 10 in the transmit side, according to the present invention, includes a unit 16 for storing previous levels and runs. As shown in FIG. 9, the

run-level pairs 102 for a given block are provided to a mapping unit 12, which map the pairs to a sequence of bins, each bin having a value of 0 or 1. The location of the bin in the sequence representing a run-level pair is called a bin number. The bin numbers are represented by signals 104. Based on the signals 104 and a previously encoded level value 108 provided by unit 16, an assignment unit 14 assigns a context to a bin number. The contexts, denoted by signals 106, are provided to an adaptive arithmetic coder 20. The probability of occurrence of 1 and the probability of occurrence of 0 are estimated by a probability estimation module 22. Based on the probability estimates 120, an arithmetic encoding unit 24 encodes the bins. A feedback signal 124 is provided from the encoder 24 to the probability estimation module 22 to update the probability estimation. The encoded information is made into a bit-stream 122 to be conveyed to a decoder or stored in a storage device for later use.

Preferably, the encoder 10 also includes a unit 18, which is capable of providing the number, N_c , of non-zero coefficients in the block to the arithmetic encoder 20 before the run-level pairs are provided to the arithmetic encoder 20, so that N_c is also encoded and included into the bit-stream 122. N_c is represented by signals 110. By using N_c , there is no need to send an End-of-Block (EOB) symbol to the decoder. In prior art, the level value of 0 is used for the EOB symbol. More specifically, N_c is found after transform and quantization and it is encoded with entropy encoding. It should be noted that with the number of non-zero coefficients known, it is no longer necessary to use the 0-level value to signal the end of the block. Thus, it is possible to modify the level value by subtracting the value of the quantized coefficient by 1.

On the receive side, as shown in FIG. 10, a decoder 50 is used to receive the bit-stream 122 provided by the encoder 10. The received bit-stream, which represents arithmetic coded data symbols, is denoted by reference numeral 202. Initially, based on the previously decoded symbols, a context is calculated in a context assignment block 66 and the probability estimates of the bin values are updated in a probability estimation block 62. The previously decoded symbols based on which the probability estimates are updated are denoted by reference numeral 205. Context assignment, as carried out in the context assignment block 66, and calculation of probability estimates, as carried out in the probability estimation block 62, are similar to those in the encoder 10. The received bits 202 are then fed into an arithmetic decoding engine 64 in an arithmetic coder 60, where they are converted into decoded bin values 206, using the calculated context and the current probability estimates of the bin values 204. Decoded bins 208 are mapped to the values of the runs and levels in block 68. If the number, N_c , of non-zero coefficients in the block is encoded in the encoder 10 and provided in the received bit-stream 202, then a signal 214 is provided to the bin-to-value mapping module 68 whereby the quantized coefficient is restored by adding to the level value by 1.

FIG. 11 is a flowchart illustrating a method of image coding, according to the preferred embodiment of the present invention. As shown, the method 500 starts at step 510 where an image is received by an encoder. The received image is divided into a plurality of blocks at step 520. Each block is scanned at step 530 and the levels and runs of the quantized coefficients in the block are obtained at step 540. In contrast to prior art coding schemes, the present invention also uses the previous levels in the assignment of contexts at step 550. In particular, the assignment of contexts to the bins representing the level values of the quantized coefficients

takes into account the value of the previously encoded level, as described in section 1.1. Likewise, the assignment of contexts to the bins representing the run values of the quantized coefficients takes into account the level value, as described in section 1.2. The assigned contexts are conveyed to an arithmetic coder for encoding at step 560. Additionally, N_c , or the number of non-zero quantized coefficients, is determined during or after the block is scanned at step 530 and N_c is encoded at step 560 prior to N_c and the contexts being provided to a decoder, as described in section 1.3.

Alternatively, the image coding method can be improved solely by conveying signals indicative of N_c to the receive side, without considering the value of the previously encoded level or run when the contexts are assigned, as shown in FIG. 11. As shown in FIG. 12, instead of obtaining the previously encoded levels and runs at step 540 for assigning the contexts at step 550, N_c is obtained and provided at step 542. N_c is conveyed, before the contexts assigned at step 550 are sent, to an arithmetic coder for encoding at step 560. By sending N_c , there is no need to send the EOB symbol to the decoder.

Although the invention has been described with respect to a preferred embodiment thereof, it will be understood by those skilled in the art that the foregoing and various other changes, omissions and deviations in the form and detail thereof may be made without departing from the scope of this invention.

What is claimed is:

1. A method of image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixels to produce a corresponding block of transform coefficient values, the block of transform coefficient values being scanned in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order, the method comprising the steps of:

representing the coefficient values in the scanned array by a plurality of number pairs, each of said number pairs having a first number and a second number; and assigning the first numbers to one of a plurality of contexts representative of the first numbers such that the first number of a first number pair is assigned to a context at least partly in dependence on a first number of a second number pair.

2. A method according to claim 1, wherein the first number of the first number pair is assigned to a context at least partly in dependence on the first number of a preceding number pair in the scanning order.

3. A method according to claim 1, wherein said plurality of contexts are contexts of a context-based arithmetic coder.

4. A method according to claim 1, wherein said plurality of contexts are contexts of a context-based binary arithmetic coder.

5. A method according to claim 4, further comprising the step of:

mapping the first numbers of said number pairs to a set of bins, each of which can be assigned one of either a first or a second value.

6. A method according to claim 5, wherein mapping of a number to a given one of said set of bins is indicated by assigning the bin to the first value.

7. A method according to claim 5, wherein the first value is 1 and the second value is 0.

8. A method according to claim 5, wherein the first number of a number pairs is assigned to a context at least partly in dependence on the bin to which the first number of said number pair is mapped.

9. A method according to claim 1, wherein said first number is indicative of a non-zero coefficient value and said second number is indicative of a number of consecutive zero coefficient values preceding said non-zero coefficient value.

10. A method of image coding, wherein an image is divided in an encoder into a plurality of blocks having a plurality of pixels, each pixel having a pixel value, and a transform coding operation is performed on a block of pixels to produce a corresponding block of transform coefficient values, the block of transform coefficient values is scanned in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order, the method comprising the steps of:

representing the coefficient values in the scanned array by a plurality of number pairs, each of said number pairs having a first number and a second number; and assigning the second numbers to one of a plurality of contexts representative of the second numbers such that the second number of a number pair is assigned to a context at least partly in dependence on the first number of the number pair.

11. A method according to claim 10, wherein said plurality of contexts are contexts of a context-based arithmetic coder.

12. A method according to claim 10, wherein said plurality of contexts are contexts of a context-based binary arithmetic coder.

13. A method according to claim 12, further comprising the step of:

mapping the second numbers of said number pairs to a set of bins, each of which can be assigned one of either a first value or a second value.

14. A method according to claim 13, wherein mapping of a number to a given one of said set of bins is indicated by assigning the bin to the first value.

15. A method according to claim 13, wherein the first value is 1 and the second value is 0.

16. A method according to claim 13, wherein the second number of a number pair is assigned to a context at least partly in dependence on the bin to which the second number of the number pair is mapped.

17. A method according to claim 10, wherein said first number is indicative of a non-zero coefficient value and said second number is indicative of a number of consecutive zero coefficient values preceding said non-zero coefficient value.

18. A system for image coding comprising:

an input for receiving an image as a plurality of blocks having a plurality of pixels, each pixel having a pixel value;

a transform coder for performing a transform coding operation on a block of pixels to produce a corresponding block of transform coefficient values;

a scanner for scanning the block of transform coefficient values in a given scanning order to produce a scanned array of coefficient values, arranged according to the scanning order;

a run-level coder for representing the coefficient values in the scanned array by a plurality of number pairs, said number pairs having a first number and a second number; and

a context-based coder for assigning the first numbers to one of a plurality of contexts representative of the first numbers and operative to assign the first number of a first number pair to a context at least partly in dependence on a first number of a second number pair.

19. A system according to claim 18, wherein said context-based coder is a context-based arithmetic coder.

29

20. A system according to claim 18, wherein said context-based coder is a context-based binary arithmetic coder.

21. A system according to claim 20, wherein the context-based coder is operative to map the first numbers of said number pairs to a set of bins, each of which can be assigned to one of either a first or a second value. 5

22. A system according to claim 21, wherein the context-based coder is operative to map a number to a given one of said set of bins by assigning the bin to the first value.

23. A system according to claim 21, wherein the first value is 1 and the second value is 0. 10

24. A system according to claim 21, wherein the context-based coder is operative to assign the first number of a number pair to a context at least partly in dependence on the bin to which the first number of said number pair is mapped. 15

25. A system according to claim 18, wherein the context-based coder is operative to assign the first number of the first number pair to a context at least partly in dependence on the first number of a preceding number pair in the scanning order. 20

26. A system according to claim 18, wherein said first number is indicative of a non-zero coefficient value and said second number is indicative of a number of consecutive zero coefficient values preceding said non-zero coefficient value.

27. A system for image coding comprising: 25

an input for receiving an image as a plurality of blocks having a plurality of pixels, each pixel having a pixel value;

a transform coder for performing a transform coding operation on a block of pixels to produce a corresponding block of transform coefficient values; 30

a scanner for scanning the block of transform coefficient values in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order; 35

a run-length coder for representing the coefficient values in the scanned array by a plurality of number pairs, said number pairs having a first number and a second number; and 40

a context-based coder for assigning the second numbers to one of a plurality of contexts representative of the second numbers, and operative to assign the second number of a number pair to a context at least partly in dependence on the first number of the number pair. 45

28. A system according to claim 27, wherein said context-based coder is a context-based arithmetic coder.

29. A system according to claim 27, wherein said context-based coder is a context-based binary arithmetic coder.

30. A system according to claim 29, wherein the context-based coder is operative to map the second numbers of said number pairs to a set of bins, each of which can be assigned to one of either a first or a second value. 50

31. A system according to claim 30, wherein the context-based coder is operative to map a number to a given one of said set of bins by assigning the bin to the first value. 55

32. A system according to claim 30, wherein the first value is 1 and the second value is 0.

33. A system according to claim 30, wherein the context-based coder is operative to assign the second number of a number pair to a context at least partly in dependence on the bin to which the second number of the number pair is mapped. 60

34. A system according to claim 27, wherein said first number is indicative of a non-zero coefficient value and said second number is indicative of a number of consecutive zero coefficient values preceding said non-zero coefficient value. 65

30

35. A computer program embodied in a computer readable medium comprising:

machine-readable program code for dividing an image into a plurality of blocks having a plurality of pixels, each pixel having a pixel value;

machine-readable program code for performing a transform coding operation on a block of pixel values to produce a corresponding block of transform coefficient values;

machine-readable program code for scanning the block of transform coefficient values in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order;

machine-readable program code for representing the coefficient values in the scanned array by a plurality of number pairs, said number pairs having a first number and a second number; and

machine-readable program code for assigning the first numbers to one of a plurality of contexts representative of the first numbers such that the first number of a first number pair is assigned to a context at least partly in dependence on a first number of second number pair.

36. A computer program embodied in a computer readable medium comprising:

machine-readable program code for dividing an image into a plurality of blocks having a plurality of pixels, each pixel having a pixel value;

machine-readable program code for performing a transform coding operation on a block of pixel values to produce a corresponding block of transform coefficient values;

machine-readable program code for scanning the block of transform coefficient values in a given scanning order to produce a scanned array of coefficient values arranged according to the scanning order; 35

machine-readable program code for representing the coefficient values in the scanned array by a plurality of number pairs, said number pairs having a first number and a second number; and 40

machine-readable code for assigning the second numbers to one of a plurality of contexts representative of the second numbers such that the second number of a number pair is assigned to a context at least partly in dependence on the first number of the number pair.

37. A method of context-based arithmetic encoding in which an array of data symbols is represented with a code-word, the method comprising:

representing the data symbols in said array as number pairs comprising a first number and a second number; and

assigning the first number of a first number pair to a context selected from a plurality of contexts representative of the first numbers at least partly in dependence on a first number of a second number pair.

38. A method of context-based arithmetic encoding in which an array of data symbols is represented with a code-word, the method comprising:

representing the data symbols in said array as number pairs comprising a first number and a second number;

assigning the first number of a first number pair to a context selected from a plurality of contexts representative of the second numbers at least partly in dependence on the first number of the number pair.

39. A context-based arithmetic encoder operative to represent an array of data symbols with a code-word and comprising:

31

a run-level coder for representing the data symbols in said array as number pairs comprising a first number and a second number;

a context assigner for assigning the first number of a first number pair to a context selected from a plurality of contexts representative of the first numbers at least partly in dependence on a first number of a second number pair. 5

40. A context-based arithmetic encoder operative to represent an array of data symbols with a code-word and comprising: 10

32

a run-level coder for representing the data symbols in said array as number pairs comprising a first number and a second number;

a context assigner for assigning the second number of a number pair to a context selected from a plurality of contexts representative of the second numbers at least partly in dependence on the first number of the number pair.

ABSTRACT

A method for reducing visual artifacts in a frame of a digital
video signal, which is coded by blocks and then decoded,
includes defining a block type is according to the coding
method for a block selected according to a predetermined set
of coding types. In the method filtering is performed to
reduce visual artifacts due to a block boundary. The filtering
performed depends on block types of the frame in the
environment of the block boundary.

METHOD AND ASSOCIATED DEVICE FOR FILTERING DIGITAL VIDEO IMAGES

BACKGROUND OF THE INVENTION

1. Field of the Invention

The present invention relates to a method for reducing visual artefacts in a frame of a digital video signal, which is coded by blocks and then decoded, a block type being defined according to the coding method for a block selected from a predetermined set of coding types, in which filtering is performed to reduce visual artefacts due to a block boundary. The present invention also relates to a device for reducing visual artefacts in a frame of a digital video signal, which is coded by blocks and then decoded, a block type being defined according to the coding method for a block selected according to a predetermined set of coding types, the device comprising a filter for reducing visual artefacts due to a block boundary. Furthermore, the present invention relates to a video encoder comprising means for coding and decoding a digital video signal by blocks, a block type being defined according to the coding method for a block selected according to a predetermined set of coding types, which encoder comprises a filter for reducing visual artefacts due to a block boundary. The present invention also relates to a video decoder comprising means for reducing visual artefacts in a frame of a digital video signal, which is coded by blocks and then decoded, a block type being defined according to the coding method for a block selected according to a predetermined set of coding types, which video decoder comprises a filter for reducing visual artefacts due to a block boundary. The present invention also relates to a video codec comprising means for coding and decoding a digital video signal by blocks, a block type being defined according to the coding method for a block selected according to a predetermined set of coding types, which video codec comprises a filter for reducing visual artefacts due to a block boundary. The present invention also relates to a mobile terminal comprising a video codec, which comprises means for coding and decoding a digital video signal by blocks, a block type being defined according to the coding method for a block selected according to a predetermined set of coding types, which video codec comprises a filter for reducing visual artefacts due to a block boundary. The present invention further relates to a storage medium for storing a software program comprising machine executable steps for coding and decoding a digital video signal by blocks, a block type being defined according to the coding method for a block selected according to a predetermined set of coding types, for reducing visual artefacts due to a block boundary by filtering.

2. Brief Description of Related Developments

A transmission system like that shown in FIG. 1 is generally used for transferring a digital video image in compressed form. The video image is formed of sequential frames. In some prior art video transmission systems, for example those according to the ITU-T H.261/H.263 recommendations, at least three frame types are defined: an I-frame (Intra), a P-frame (Predicted or Inter), and a B-frame (Bi-directional). The I-frame is generated solely on the basis of information contained in the image itself, wherein at the receiving end, this I-frame can be used to form the entire image. P-frames are formed on the basis of a preceding I-frame or P-frame, wherein at the receiving stage a preceding I-frame or P-frame is correspondingly used together with the received P-frame in order to reconstruct the image. In the composition of P-frames, for instance, motion compensation

is used to compress the quantity of information. B-frames are formed on the basis of one or more preceding P-frames or I-frames and/or one or more following P- or I-frames.

The frames are further divided into blocks. One or more such blocks forms a block region. There can generally be four different region types: Intra region, copy region, coded region, and not-coded region. An intra region is a block region in which the blocks are coded independently without reference to any other frame. A copy region consists of blocks which are obtained by copying the content of the reference frame into exactly the same location without any motion compensated prediction. A coded region consists of blocks which are obtained using motion compensated prediction and prediction error coding. The prediction error is a difference between the pixel values of the actual frame and a reconstructed frame which is formed in the coding/decoding system using motion compensated prediction, as will be described in further detail later in the text. The prediction error is coded and sent to a receiver. A not-coded region is obtained using motion compensated prediction only. In fact the not-coded region is equivalent to a copy region if the motion information equals 0. All the block regions of one frame are not necessarily similar types, but one frame can comprise block regions which are of different types.

Referring to FIG. 1, which illustrates a typical encoding and decoding system (codec) used, for example, in the transmission of digital video, a current video frame to be coded comes to the transmission system 10 as input data $I_n(x,y)$. The input data $I_n(x,y)$ typically takes the form of pixel value information. In the differential summer 11 it is transformed into a prediction error frame $E_n(x,y)$ by subtracting from it a prediction frame $P_n(x,y)$ formed on the basis of a previous image. The prediction error frame is coded in block 12 in a manner described hereinafter, and the coded prediction error frame is directed to a multiplexer 13. To form a new prediction frame, the coded prediction error frame is also directed to a decoder 14, which produces a decoded prediction error frame $\hat{E}_n(x,y)$ which is summed in a summer 15 with the prediction frame $P_n(x,y)$, resulting in a decoded frame $\hat{I}_n(x,y)$. The decoded frame is saved in a frame memory 16. To code the next frame, the frame saved in the frame memory 16 is read as a reference frame $R_n(x,y)$ and is transformed into a new prediction frame $P_n(x,y)$ in a motion compensation and prediction block 17, according to the formula:

$$P_n(x,y) = R_n[x + Dx(x,y), y + Dy(x,y)] \quad (1)$$

The pair of numbers $[Dx(x,y), Dy(x,y)]$ is called the motion vector of the pixel at location (x,y) and the numbers $Dx(x,y)$ and $Dy(x,y)$ are the horizontal and vertical shifts of the pixel. They are calculated in a motion estimation block 18. The set of motion vectors $[Dx(\bullet), Dy(\bullet)]$ consisting of all motion vectors related to the pixels of the frame to be compressed is also coded using a motion model comprising basis functions and coefficients. The basis functions are known to both the encoder and the decoder. The coefficient values are coded and directed to the multiplexer 13, which multiplexes them into the same data stream with the coded prediction error frame for sending to a receiver. In this way the amount of information to be transmitted is dramatically reduced.

Some frames can be partly, or entirely, so difficult to predict that it is not practical to use motion compensated prediction when coding them. These frames or parts of frames are coded using intra-coding without prediction, and therefore it is not necessary to send motion vector information relating to them to the receiver.

In the receiver system 20, a demultiplexer 21 separates the coded prediction error frames and the motion information transmitted by the motion vectors and directs the coded prediction error frames to a decoder 22. The decoder 22 produces a decoded prediction error frame $\hat{E}_n(x,y)$, which is summed in a summer 23 with the prediction frame $P_n(x,y)$ formed on the basis of a previous frame, resulting in a decoded frame $\hat{I}_n(x,y)$. The decoded frame is directed to an output 24 of the decoder and at the same time saved in a frame memory 25. When decoding the next frame, the frame saved in the frame memory is read as a reference frame and transformed into a new prediction frame in the motion compensation and prediction block 26, according to formula (1) presented above.

The coding method applied in block 12 to the coding of the prediction error frame or to the intra-coding of a frame or part of a P-frame to be sent without prediction, is generally based on a transformation, the most common of which is the Discrete Cosine Transformation, DCT. The frame is divided into adjacent blocks having a size of e.g. 8x8 pixels. In coding and decoding, the blocks are processed independent of one another. The transformation is calculated for the block to be coded, resulting in a series of terms. The coefficients of these terms are quantized on a discrete scale in order that they can be processed digitally. Quantization causes rounding errors, which can become visible in an image reconstructed from blocks, so that there is a discontinuity of pixel values at the boundary between two adjacent blocks. Because a certain decoded frame is used for calculating the prediction frame for subsequent predicted frames, these errors can be propagated in sequential frames, thus causing visible edges in the image reproduced by the receiver. Image errors of this type are called blocking artefacts.

Some prior art methods are known for removing blocking artefacts. These methods are characterized by the following features:

- determining which pixel/pixels require value correction in order to remove the blocking artefact,
- determining a suitable low-pass filtering for each pixel to be corrected, based on the values of other pixels contained by a filtering window placed around the pixel,
- calculating a new value for the pixel to be corrected, and rounding the new value to the closest digitized pixel value.

Factors that influence the selection of a filter and the decision whether to use filtering can be, for example, the difference between the values of pixels across the block boundary, the size of the quantization step of the coefficients received as the transformation result, and the difference of the pixel values on different sides of the pixel being processed.

It has been found that prior art methods tend to remove lines that belong to real features of the image. On the other hand, prior art methods are not always capable of removing all blocking artefacts.

SUMMARY OF THE INVENTION

An objective of the present invention is to present a new kind of filtering arrangement for reducing blocking artefacts. The invention also has the objective that the method and associated device operate more reliably and efficiently than prior art solutions.

The method according to the invention adjusts filtering parameters according to the type of blocks whose boundary

is to be filtered. Different filtering parameters are chosen according to the type of block on either side of the boundary in order to yield an improved filtering result.

The objectives of the invention are achieved by adapting the selection of pixels for filtering and the filtering process more flexibly than before to the features of the frame and the environment of the filtering point and by taking into account the nature/type of the blocks to be filtered.

According to a first aspect of the invention, there is provided a method for reducing visual artefacts in a frame that is coded by blocks, characterized in that the filtering performed on the block boundary depends on block types of the frame in the environment of the block boundary.

According to a second aspect of the invention, there is provided a device for implementing the method according to the invention. The device according to the invention is characterized in that the filter is arranged to operate adaptively according to the block types of the frame in the environment of the block boundary.

According to a third aspect of the invention, there is provided an encoder characterized in that the filter is arranged to operate adaptively according to the block types of the frame in the environment of the block boundary.

According to a fourth aspect of the invention, there is provided a decoder characterized in that the filter is arranged to operate adaptively according to the block types of the frame in the environment of the block boundary.

According to a fifth aspect of the invention, there is provided a codec characterized in that the filter is arranged to operate adaptively according to the block types of the frame in the environment of the block boundary.

According to a sixth aspect of the invention, there is provided a mobile terminal characterized in that the filter is arranged to operate adaptively according to the block types of the frame in the environment of the block boundary.

According to a seventh aspect of the invention, there is provided a storage medium characterized in that the software program further comprises machine executable steps for filtering adaptively according to the block types of the frame in the environment of the block boundary.

Because blocking artefacts only occur at block boundaries, according to the invention, filtering is advantageously only applied to pixels at block boundaries and the vicinity thereof. Edges that are part of the image can reside anywhere in the image area. In order that only pixels containing blocking artefacts are selected for corrective filtering and that the quality of edges that are part of the image itself is not affected during filtering, the following assumptions are made:

Changes in pixel values associated with edges that are part of the image are generally larger than those associated with blocking artefacts, and those edges within the image, where the pixel value change is small, do not suffer considerably from the rounding of the pixel value difference caused by filtering.

Because the image to be coded is generally divided into blocks both vertically and horizontally, the image contains both vertical and horizontal block boundaries. With regard to vertical block boundaries, there are pixels to the right and left of the boundary, and with regard to horizontal block boundaries, there are pixels above and below the boundary. In general, the location of the pixels can be described as being on a first or a second side of the block boundary. In an exemplary embodiment of the filtering method according to the invention, the number of pixels to be corrected, the characteristic features of the filter being used and the size of the filtering window depend on the following factors:

5

- a) The type of block on either side of the boundary (e.g. inter, copy, coded, not-coded),
- b) the difference in pixel values Δ across the block boundary. The difference can be defined in many ways. One definition is $\Delta = |r_1 - l_1|$, where r_1 is the value of the pixel on the first side of the block boundary closest to the boundary, and l_1 is the value of the pixel on the second side of the block boundary closest to the boundary,
- c) the size of the quantization step OP of the coefficients received as the result of the transformation used in coding, and
- d) differences in pixel values between the pixels on the first side of the block boundary, and correspondingly between the pixels on the second side of the block boundary.

In an advantageous embodiment of the method according to the invention, the number of the pixels selected for filtering can vary, and it is not necessarily the same on different sides of a block boundary. The number of pixels also depends on the type of block on either side of the boundary. Because the number of pixels is adapted to the general features of the image information contained by the frame in a particular region according to the factors mentioned above, the method produces a better filtering result than that provided by prior art methods. A "better" result in this context is one in which blocking artefacts are reduced to a greater extent while real edges in the image are affected to a lesser degree. This means that a larger amount of blocking artefacts can be removed without weakening the real image edges unreasonably.

It should be noted that in other embodiments of the invention, the factors affecting the filtering performed at a block boundary may differ from those presented above.

BRIEF DESCRIPTION OF THE DRAWINGS

In the following, the invention will be described in more detail with reference to the preferred embodiments and the accompanying drawings, in which

FIG. 1 represents a digital video encoding and decoding system (codec) according to prior art,

FIG. 2 represents the location of pixels in relation to a block boundary in an exemplary embodiment of the method according to the invention,

FIG. 3 represents alternatives for locating the filtering method according to the invention in a digital video encoding and decoding system,

FIG. 4 is a schematic representation of a device for implementing a method according to the invention,

FIG. 5 represents a device according to FIG. 4 in operation, and

FIG. 6 is a schematic representation of a portable video telecommunications device implementing a method according to the invention.

DETAILED DESCRIPTION OF THE PREFERRED EMBODIMENT(S)

In the above, in connection with the description of the prior art, reference was made to FIG. 1. In the following description of the invention and its preferred embodiments, reference will be made mostly to FIGS. 2 to 5. The same reference numbers are used for corresponding parts in the figures.

FIG. 2 shows the location of the pixels r_1 - r_6 and l_1 - l_6 in relation to a vertical block boundary 30. To implement the method according to the invention, certain parameters are

6

specified. Parameter n is the largest number of pixels to be examined from the block boundary in one direction, and in the case of FIG. 2 its value is 6. It is advantageous to select the value of the parameter n so that it has a certain relation to both the difference of the pixel values Δ across the block boundary and to the size of the quantization step QP of the coefficients received as the result of image coding. Furthermore, the value of parameter n is advantageously smaller than or equal to the number of pixels in the block in the direction of examination, to avoid possible blocking artefacts associated with previous block boundaries spreading to the block boundary under examination. The following definition is recommended for use in a preferred embodiment of the invention applied to image blocks comprising 8x8 pixels:

$$n = \begin{cases} 0 & \Delta \geq 2.00\alpha \\ 1 & 1.50\alpha \leq \Delta < 2.00\alpha \\ 2 & 1.00\alpha \leq \Delta < 1.50\alpha \\ 3 & 0.66\alpha \leq \Delta < 1.00\alpha \\ 4 & 0.40\alpha \leq \Delta < 0.66\alpha \\ 5 & 0.25\alpha \leq \Delta < 0.40\alpha \\ 6 & 0 \leq \Delta < 0.25\alpha \end{cases} \quad (2)$$

wherein $\alpha = \text{QP} \cdot \log(\text{QP})$. If QP has a different value in blocks on different sides of the block boundary, the smaller value of QP is used in the calculations, as well as in all cases presented hereinafter, in which a definition includes reference to one OP value only. The invention does not place any limitations on the determination of the value of parameter n, but according to the guidelines of equation (2), it is advantageous that its value is generally higher when the difference of pixel values Δ across the block boundary is small in comparison with the size of the quantization step OP of the coefficients received as the result of the coding transformation. If the difference between the pixel values Δ is large, there is a high probability that there is a real image edge at the block boundary, and in this case the pixels are preferably not examined for filtering at all ($n=0$).

In the next step of the filtering method according to the invention, region type information concerning the two neighbouring blocks is examined, i.e. the type of the blocks on both sides of the block boundary in question is considered. According to the region type information, the value of the parameter n may further be limited (truncated) to provide even better results for reducing blocking artefacts. The region type information is included e.g. in the coded information relating to the pixels of a particular block, wherein that information is maintained, or temporarily stored, during decoding of the block until a truncated value n_{tr} for parameter n is determined.

Table 1 shows truncation values according to an advantageous embodiment of the present invention. Table 1 applies in a situation where the maximum value of n is 6, and, of course, different truncated values would be appropriate in situations where the maximum value is other than 6. The truncation values are used for the first and second sides of the block boundary depending on the region type of the block on the first side of the block boundary and on the region type of the block on the second side of the block boundary.

TABLE 1

type of the Block on the First side of a boundary	type of the Block on the Second side of a boundary							
	INTRA		COPY		CODED		NOT_CODED	
INTRA	n	n	2	2	n	4	n	2
COPY	2	2	2	2	2	4	2	2
CODED	4	n	4	2	4	4	4	2
NOT_CODED	2	n	2	2	2	4	2	2

Each cell of Table 1, corresponding to a particular region type combination, is split into two parts. The value on the left gives the truncation value $trval$ for the first side of the block boundary and the value on the right gives the truncation value $trval$ for the second side of the boundary. If the value of parameter n exceeds the value given in Table 1, n is truncated to the truncation value $trval$ in Table 1. If, however, the value of the overall activity parameter n does not exceed the value given in Table 1, the value of the parameter n (originally determined from equation (2)) is retained. In Table 1 the symbol “n” indicates that further truncation is not performed and the parameter value is retained. The truncated value n_{tr} for the parameter n can also be represented by the formula:

$$n_{tr} = \min(trval, n), \quad (3)$$

The same table can be used both for filtering across vertical block boundaries (horizontal filtering) by putting “Left”/“Right” in place of “First”/“Second” and for filtering across horizontal block boundaries (vertical filtering) by putting “Bottom”/“Up” in place of “First”/“Second”, respectively. Now, the value on the left gives the truncation value for the pixels on the left/below the block boundary, and the value on the right gives the truncation value for the pixels on the right/above the boundary.

To further clarify the use of Table 1, an example situation is presented in the following. In this illustrative example situation “horizontal filtering” is performed across a vertical block boundary 30. Assuming that the value for parameter n , calculated from equation 2, is e.g. 4, the block on the left-hand side of the block boundary 30 in question is of the Intra type, and the block on the right-hand side of the block boundary 30 in question is of the Not-coded type, Table 1 indicates that the truncation value for the left-hand side is n and the truncation value for the right-hand side is 2. This means that the 4 pixels closest to the block boundary (=the calculated value of n) are selected for examination from the left-hand side of the boundary, and 2 pixels closest to the block boundary (=the truncated value of n) are selected for examination from the right-hand side.

Another example situation is presented in the following. In this illustrative example situation “horizontal filtering” is performed across a vertical block boundary 30. Assuming that the value of parameter n calculated from equation (2) is e.g. 4, and the blocks on both sides of the block boundary 30 in question are of the Copy type, Table 1 indicates that the truncation value for the left-hand side is 2 and the truncation value for the right-hand side is 2. This means that the 2 pixels closest to the block boundary (=the truncated value of n) are selected for examination from the left-hand side of the boundary, and the 2 pixels closest to the block boundary (=the truncated value of n) are selected for examination from the right-hand side.

For bi-directionally predicted frames (B-frames), truncation of the parameter n is advantageously not applied because there is no unique block type information.

The next step in the filtering method according to the invention is to determine the values of the parameters d_r and d_l , which represent activity, or the differences of pixel values between pixels on one side of the block boundary. A preferred definition for d_r is the following:

$$d_r = 6, \text{ if } |r_1 - r_j| \leq \beta/j \text{ with all } j \in [1, 6],$$

otherwise: $d_r = i$, where i fulfils the conditions

$$i \in [1, n_{tr}],$$

$$|r_1 - r_{i+1}| > \beta/i \text{ and}$$

$$|r_1 - r_j| \leq \beta/j \text{ with all } j \in [1, i]. \quad (4)$$

Here, the auxiliary parameter $\beta = 4 \cdot \log(QP)$. The value of parameter d_l is determined similarly, except that all r 's are replaced by l 's and the corresponding truncated value n_{tr} for the parameter n must be used. The number 6 appears in definition (4) because, according to equation (2), the highest possible value of n is 6 in this case. If n is defined differently, but the parameters d_r and d_l are defined according to definition (4), the number 6 must be replaced by the highest possible value of n according to the new definition.

It is advantageous that the values of the parameters d_r and d_l are calculated independent of one another, because the image information contained by the frame can be different on different sides of the block boundary. The invention does not limit the definition of parameters d_r and d_l , but according to the guidelines of definition (4), it is advantageous that these parameters are used to limit the blocking artefact processing relatively close to the block boundary, if there is a real image edge near the block boundary. The essential features of definition (4) can be summarised as follows: the value of parameter d_r (and correspondingly the value of parameter d_l) provides an indication of how many pixels counted from the block boundary have approximately the same value as the pixel at the block boundary.

A high value of parameter n (e.g. 6) indicates that the difference between the pixel values at the block boundary is relatively small compared with the general variation of the pixel values within the block. In this case, it is possible that there is a real image edge near the block boundary. By selecting a sufficiently small value of parameter d_r (or d_l), it is possible to restrict the filtering aimed at correcting blocking artefacts so that it does not have a deteriorating effect on a real image edge close to the block boundary. In some situations, a large number of pixels counted from the block boundary have approximately the same value as the pixel at the block boundary. In that case, definition (4) would give the parameter d_r (or d_l) a relatively high value. However, if there is a clear discontinuity in pixel values between the blocks, the parameter n has a small value and the truncated value n_{tr} is used in the definition (4) which make sure that an unreasonably high value is not selected as the value of the parameter d_r (or d_l). Otherwise, a relatively high value of the parameter d_r (or d_l) would result in unnecessary filtering.

If blocks on both sides of the block boundary are Intra-type blocks, the truncation has no effect on the selection of the parameter values n , d_r and d_l . On the other hand, if at least one of the blocks has a type other than Intra, the truncation of the value n according to the formula (3) may limit the number of pixels filtered. This has the advantage that the block boundaries are not smoothed too much.

In addition, the largest possible number of pixels to be filtered must be decided. This does not have a notation of its own in FIG. 2, but it can be e.g. 3, which means that filtering can only be used to correct the value of the pixels r_1 , r_2 , r_3 , l_1 , l_2 and l_3 .

When the values of the parameters n , n_r , d_r and d_l have been determined, filtering is carried out using a suitable filter. The invention does not limit the kind of filter that can be used, but a filtering arrangement that has been found preferable, will be described in the following. Filtering is used to determine a new value for the pixels selected for filtering. In a preferred embodiment of the invention, a new pixel value is determined for a given pixel by calculating the mean of the pixel values that appear in a filtering window. In the preferred embodiment, the filtering window is symmetrical with regard to the pixel to be filtered and contains, in addition to the pixel to be filtered, one, two or three pixels from both sides, depending on the values of the parameters d_r and d_l as described hereinafter. Of course, these are only examples and other values could be chosen in situations where n , n_r , d_r and d_l are defined differently. The calculated mean value is rounded to the closest digitized pixel value, whereby it becomes the new value of the filtered pixel.

Table 2 shows the determination of the width of the filtering window for the pixels r_1 , r_2 and r_3 according to the value of parameter d_r in a preferred embodiment of the invention. The values of the pixels l_1 , l_2 and l_3 are determined in the same manner according to the value of the parameter d_l . In the table, "X" means that the pixel in question is not filtered at all, and the number means that the filtering window includes a number of pixels shown by the number from each side of the pixel being examined. Among other things, Table 2 shows that for filtering to be applied to any pixel, parameters d_r and d_l must both have a value greater than 1.

d_r ($d_l > 1$)	r_1	r_2	r_3
1	X	X	X
2	1	X	X
3	1	1*	X
4	2	2	X

*the filtered value of pixel r_1 is used for filtering of pixel r_2

**the filtered values of pixels r_1 and r_2 are used for filtering pixel r_3

***3 if $d_r > 2$, otherwise 2.

The above description relates to implementing the filtering on one horizontal part of a pixel row, which is 12 pixels long and located symmetrically on both sides of a vertical block boundary. The description can be easily generalized to concern vertical parts of pixel columns, which are located symmetrically on both sides of a horizontal block boundary: FIG. 2 can be turned 90 degrees counter-clockwise, whereby block boundary 30 becomes horizontal, and the pixels shown in the figure form part of the vertical pixel column so that pixels r_1 - r_6 are the pixels above and pixels l_1 - l_6 are the pixels below the boundary. To filter block boundaries throughout the whole frame, applying the method according to the invention, all vertical block boundaries of the frame are examined row by row and all horizontal block boundaries are examined column by column. The order has no significance as such, and thus all the horizontal block boundaries of the frame could be examined first column by column, and then all the vertical block boundaries row by row. In an advantageous embodiment of the invention, filtering is repeated line by line, i.e. the first line of the pixels in the blocks (besides the boundary) is filtered first, then the second line, etc.

FIG. 3 shows at which points a digital image encoding and decoding system (codec) according to prior art can be

improved by applying filtering according to the invention. The first alternative is to place a block implementing the filtering method according to the invention in the output of the decoder of the receiver, as illustrated by reference number 31. In this case, block boundaries in the video frame are filtered after all blocks within the frame have been decoded. This requires block type information to be stored for all the blocks in one frame. Another alternative is to place the filtering block in the receiver before the point at which the decoded frame is directed to the frame memory 25 for forming a prediction frame, as illustrated by reference number 32. In this case, block type information for all blocks within the frame must also be stored, as block boundary filtering is still performed after decoding and reconstructing the entire frame. However, this alternative has the advantage that the removal of blocking artefacts also has an effect on the formation of a prediction frame, whereby blocking artefacts in one frame are not propagated via the prediction frame to subsequent frames. In order to achieve the effect just described, the block that performs filtering according to the invention can be placed either before or after the frame memory 25. However, the location shown by reference number 32 is preferred, because when applied at this stage, the filtering influences simultaneously the frame to be output by the receiving decoder and the frame to be saved in the memory. In the transmitter, a block implementing the filtering method according to the invention can be placed as shown by reference numbers 33 and 34, either before or after the frame memory 16. In this way, the invention can also be used to produce a corrected prediction frame at the transmission end.

In a particularly advantageous embodiment of the invention, the block carrying out the filtering according to the invention is implemented in a digital signal processor or a corresponding device suited for processing a digital signal, which can be programmed to apply predetermined processing functions to a signal received as input data. FIG. 4 presents the functional elements of a block carrying out the filtering method according to the invention, implemented as a digital signal processor. Correspondingly, operation of the filtering block is illustrated by FIG. 5. Referring first to FIG. 4, the functional elements are programmed with functional definitions (35-39) for calculating the parameters that control the filtering method according to the invention. Advantageously, the functional definitions are loaded into the signal processor in connection with its manufacture or programming. During operation according to FIG. 5, the frame is saved temporarily in register 41, so that it can be processed by the signal processor. Processing of the frame proceeds block-by-block. At a given instant, a number of pixels indicated by the parameter n , n_r , according to the definitions provided in Table 1, are selected to be examined 42 from each side of a certain point on a certain block boundary, the d -parameters 43 are calculated, and filtering 44 is performed. These operations are repeated until all boundaries of all blocks have been filtered/processed, after which the frame can be output from register 41 and a new frame saved for processing. The measures according to FIGS. 4 and 5 can be carried out in a separate signal processor or they can be implemented in a general processor which also contains other arrangements for signal processing.

A storage medium can be used for storing a software program comprising machine executable steps for performing the method according to the invention. In an advantageous embodiment of the invention, the software program is

11

read from the storage medium to a device comprising programmable means, e.g. a processor, for performing the method of the invention.

The invention can be modified without departing from the scope defined by the claims presented hereinafter, using the capabilities of a person skilled in the art without actual inventive steps. For example, the parameter Δ can be calculated using the formula $\Delta = |r_1 + r_2| - (l_1 + l_2)$ or some other formula considered suitable. The definitions of the other parameters presented above should also be considered as examples only. A particularly advantageous use of the invention is in mobile video telecommunication applications, digital television receivers and other devices that at least receive and decode digital video image. It should further be noted that in general the method according to the invention may be applied to any image coding method in which an image is encoded/decoded on a block-by-block basis, including individual (i.e. still) digital images.

FIG. 6 shows a mobile terminal 46 intended for use as a portable video telecommunications device and applying the method according to the invention. Advantageously, the mobile terminal 46 comprises at least display means 47 for displaying images, audio means 48 for capturing and reproducing audio information, a keyboard 49 for inputting e.g. user commands, a radio part 50 for communicating with a mobile communications network (not shown), processing means 51 for controlling the operation of the device, memory means 52 for storing information, and preferably a camera 53 for taking images.

The present invention is not solely restricted to the above presented embodiments, but it can be modified within the scope of the appended claims.

What is claimed is:

1. A method, comprising:

decoding a first encoded image block, which has been encoded using a first type of prediction encoding method, and a second encoded image block, which has been encoded using a second type of prediction encoding method, in accordance with their respective prediction encoding methods to form a first decoded image block and a second decoded image block, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, a block boundary being formed between the first and second decoded image blocks, the first decoded image block being on a first side of the block boundary, the second decoded image block being on a second side of the block boundary;

providing information on the first and second prediction encoding methods to a block boundary filter; and

performing, by the block boundary filter, an adaptive block boundary filtering operation on the block boundary formed between the first decoded image block on the first side of the block boundary and the second decoded image block on the second side of the block boundary, the method further comprising:

determining, by the block boundary filter, a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary as a parameter of the adaptive block boundary filtering operation, based on the types of the first and the second prediction encoding methods.

12

2. A method according to claim 1, wherein the adaptive block boundary filtering operation performed on the block boundary by the block boundary filter is dependent at least in part on a region type of an image block on a first side of the block boundary and a region type of an image block on a second side of the block boundary.

3. A method according to claim 1, wherein the number of pixels selected for examination depends on a difference in pixel value between pixels across the block boundary.

4. A method according to claim 1, wherein the number of pixels selected for examination depends on the size of a quantization step used to quantize coefficients used in encoding the image blocks.

5. A method according to claim 1, comprising selecting certain pixels to be filtered and determining a new value for each pixel to be filtered on the basis of pixels that appear in a filtering window set around the pixel.

6. A method according to claim 5, wherein the new value of the pixel is the mean value of the pixels that appear in the filtering window.

7. A method according to claim 1, comprising selecting pixels to be filtered from the pixels selected for examination.

8. A method according to claim 1, wherein the first and second prediction encoding methods are of the same type.

9. A digital signal processor configured to perform a method for reducing visual artefacts due to block boundaries according to claim 1.

10. A block boundary filter configured to perform an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, the block boundary filter being configured to receive information on the types of the first and second prediction encoding methods, and to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary as a parameter of the adaptive block boundary filtering operation, based on the types of the first and the second prediction encoding methods.

11. A block boundary filter according to claim 10, configured to perform said adaptive block boundary filtering operation on the block boundary in dependence at least in part on a region type of an image block on a first side of the block boundary and a region type of an image block on a second side of the block boundary.

12. A block boundary filter according to claim 10, further configured to select said number of pixels for examination in dependence on the difference in pixel value between pixels across the block boundary.

13. A block boundary filter according to claim 10, wherein the filter is configured to select a number of pixels for examination in dependence on the size of a quantization step used to quantize coefficients used in encoding the image blocks.

14. A block boundary filter according to claim 10, wherein the filter is configured to select certain pixels to be filtered

13

and to determine a new value for each pixel to be filtered on the basis of pixels that appear in a filtering window set around the pixel.

15 15. A block boundary filter according to claim 14, wherein the filter is configured to calculate the new value for each pixel to be filtered as a mean value of the pixels that appear in the filtering window.

16. A block boundary filter according to claim 10, wherein the first and second prediction encoding methods are of the same type.

17. A video encoder comprising a coding block, a decoding block and a prediction block for prediction encoding a frame of a digital video signal by blocks, the video encoder comprising a block boundary filter for reducing visual artifacts due to a block boundary between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the block boundary filter is configured to receive information on the selected type of the first prediction encoding method and the selected type of the second prediction encoding method and to operate adaptively according to the block types of the frame in the environment of the block boundary to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the filtering operation, based on the selected types of the first and second prediction encoding method.

18. A video decoder comprising a decoding block and a prediction block for decoding a frame of a digital video signal by blocks, the video decoder comprising a block boundary filter for reducing visual artifacts due to a block boundary between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the block boundary filter is configured to receive information on the selected type of the first prediction encoding method and the selected type of the second prediction encoding method, and to operate adaptively according to the block types of the frame in the environment of the block boundary to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the filtering operation, based on the selected types of the first and second prediction encoding method.

19. A video codec comprising a coding block, a decoding block and a prediction block for prediction encoding a frame of a digital video signal by blocks, a block type being defined according to the prediction encoding method for a block selected according to a predetermined set of coding

14

types, the video codec comprising a block boundary filter for reducing visual artifacts due to a block boundary between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the block boundary filter is configured to receive information on the selected type of the first prediction encoding method and the selected type of the second prediction encoding method, and to operate adaptively according to the block types of the frame in the environment of the block boundary to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the filtering operation, based on the selected types of the first and second prediction encoding method.

20. A mobile terminal comprising a video codec, the video codec comprising a coding block, a first decoding block and a first prediction block for prediction encoding a frame of a digital video signal by blocks, and a second decoding block and a second prediction block for decoding a prediction encoded frame of the digital video signal by blocks, a block type being defined according to the prediction encoding method for a block selected according to a predetermined set of coding types, the video codec comprising a block boundary filter for reducing visual artifacts due to a block boundary between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the block boundary filter is configured to receive information on the selected type of the first prediction encoding method and the selected type of the second prediction encoding method, and to operate adaptively according to the block types of the frame in the environment of the block boundary to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the filtering operation, based on the selected types of the first and second prediction encoding method.

21. A storage medium comprising a software program for reducing visual artifacts due to block boundaries between decoded image blocks in a frame of a digital video signal, the software program comprising machine executable code for performing an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first

15

type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the software program comprises machine executable code for receiving information on the selected type of the first prediction encoding method and the selected type of the second prediction encoding method and machine executable code for determining a first number of pixels to be filtered on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the adaptive block boundary filtering operation, based on the selected types of the first and second prediction encoding method.

22. A storage medium according to claim 21, wherein the first and second prediction encoding methods are of the same type.

23. A method of video encoding comprising:

performing an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary using an adaptive block boundary filter, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, the adaptive block boundary filtering operation comprising:

examining, by the adaptive block boundary filter, the type of the first prediction encoding method and the type of the second prediction encoding method; and

determining, by the adaptive block boundary filter, a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the filtering operation, based on the types of the first and second prediction encoding methods.

24. A method of video encoding according to claim 23, wherein the first and second prediction encoding methods are of the same type.

25. A method of video decoding, comprising:

performing an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary using an adaptive block boundary filter, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, the block boundary filtering operation comprising:

examining, by the adaptive block boundary filter, the type of the first prediction encoding method and the type of the second prediction encoding method; and

16

determining, by the adaptive block boundary filter, a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary as a parameter of the filtering operation based on the types of the first and second prediction encoding method.

26. A method of video decoding according to claim 25, wherein the first and second prediction encoding methods are of the same type.

27. A video encoder comprising an adaptive block boundary filter configured to perform an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the adaptive block boundary filter is configured to examine the type of the first prediction encoding method and the type of the second prediction encoding method, and to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the adaptive block boundary filtering operation, based on the types of the first and second prediction encoding method.

28. A video encoder according to claim 27, wherein the first and second prediction encoding methods are of the same type.

29. A video decoder comprising an adaptive block boundary filter configured to perform an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the adaptive block boundary filter is configured to examine the type of the first prediction encoding method and the type of the second prediction encoding method, and to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the adaptive block boundary filtering operation, based on the types of the first and second prediction encoding method.

30. A video decoder according to claim 29, wherein the first and second prediction encoding methods are of the same type.

31. A video codec comprising an adaptive block boundary filter configured to perform an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having

17

been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the adaptive block boundary filter is configured to examine the type of the first prediction encoding method and the type of the second prediction encoding method, and to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the adaptive block boundary filtering operation, based on the types of the first and second prediction encoding method.

32. A video codec according to claim 31, wherein the first and second prediction encoding methods are of the same type.

33. A mobile terminal comprising an adaptive block boundary filter configured to perform an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the adaptive block boundary filter is configured to examine the type of the first prediction encoding method and the type of the second prediction encoding method, and to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the adaptive block boundary filtering operation, based on the types of the first and second prediction encoding method.

34. A mobile terminal according to claim 33, wherein the first and second prediction encoding methods are of the same type.

35. A digital signal processor comprising a filtering block configured to perform an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, wherein the filtering block is configured to examine the type of the first prediction encoding method and the second prediction encoding method, and to determine a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a

18

parameter of the adaptive block boundary filtering operation, based on the types of the first and second prediction encoding method.

36. A method, comprising performing a filtering operation on a block boundary that is dependent at least in part on a first prediction encoding method used to encode first image block on a first side of the block boundary and a second prediction encoding method used to encode a second image block on a second side of the block boundary, wherein the first and the second prediction encoding methods are selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding.

37. A apparatus comprising a filter configured to examine a prediction encoding method used to encode a first image block on a first side of a block boundary and a prediction encoding method used to encode a second image block on a second side of the block boundary and to perform a filtering operation on the block boundary in dependence at least in part on the first prediction encoding method used to encode the first image block on the first side of the block boundary and the second prediction encoding method used to encode the second image block on the second side of the block boundary, wherein the first and the second prediction encoding methods are selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding.

38. A video encoder comprising a filter according to claim 37.

39. A video decoder comprising a filter according to claim 37.

40. A mobile terminal comprising a filter according to claim 37.

41. A method comprising:

using an adaptive block boundary filter to perform an adaptive block boundary filtering operation on a block boundary formed between a first decoded image block on a first side of the block boundary and a second decoded image block on a second side of the block boundary, the first decoded image block having been encoded using a first type of prediction encoding method and the second decoded image block having been encoded using a second type of prediction encoding method, the first type of prediction encoding method and the second type of prediction encoding method being selected from a group of prediction encoding methods comprising at least: intra coding, copy coding, motion-compensated prediction coding, and not-coded coding, the method further comprising: receiving, by the adaptive block boundary filter, information on the type of the first prediction encoding method and the type of the second prediction encoding method, and

determining, by the adaptive block boundary filter, a first number of pixels to be examined on the first side of the block boundary and a second number of pixels to be examined on the second side of the block boundary, as a parameter of the filtering operation, based at least in part upon the types of the first and second prediction encoding methods.

(57) **ABSTRACT**

A method of encoding a video signal representing a sequence of pictures, the method employing both non-temporal prediction and temporal prediction, wherein the method comprises, for each picture that forms a reference picture for the temporal prediction of another picture, associating with each such picture an indicator indicating the temporal order of the reference picture in the encoded video signal relative to the other reference pictures in the encoded video signal.

VIDEO CODING

BACKGROUND OF THE INVENTION

This invention relates to video coding.

A video sequence consists of a series of still pictures or frames. Video compression methods are based on reducing the redundant and perceptually irrelevant parts of video sequences. The redundancy in video sequences can be categorised into spectral, spatial and temporal redundancy. Spectral redundancy refers to the similarity between the different colour components of the same picture. Spatial redundancy results from the similarity between neighbouring pixels in a picture. Temporal redundancy exists because objects appearing in a previous image are also likely to appear in the current image. Compression can be achieved by taking advantage of this temporal redundancy and predicting the current picture from another picture, termed an anchor or reference picture. Further compression is achieved by generating motion compensation data that describes the motion between the current picture and the previous picture.

However, sufficient compression cannot usually be achieved by only reducing the inherent redundancy of the sequence. Thus, video encoders also try to reduce the quality of those parts of the video sequence which are subjectively less important. In addition, the redundancy of the encoded bit-stream is reduced by means of efficient lossless coding of compression parameters and coefficients. The main technique is to use variable length codes.

Video compression methods typically differentiate between pictures that utilise temporal redundancy reduction and those that do not. Compressed pictures that do not utilise temporal redundancy reduction methods are usually called INTRA or I-frames or I-pictures. Temporally predicted images are usually forwardly predicted from a picture occurring before the current picture and are called INTER or P-frames. In the INTER frame case, the predicted motion-compensated picture is rarely precise enough and therefore a spatially compressed prediction error frame is associated with each INTER frame. INTER pictures may contain INTRA-coded areas.

Many video compression schemes also use temporally bi-directionally predicted frames, which are commonly referred to as B-pictures or B-frames. B-pictures are inserted between anchor picture pairs of I- and/or P-frames and are predicted from either one or both of these anchor pictures. B-pictures normally yield increased compression as compared with forward-predicted pictures. B-pictures are not used as anchor pictures, i.e., other pictures are not predicted from them. Therefore they can be discarded (intentionally or unintentionally) without impacting the picture quality of future pictures. Whilst B-pictures may improve compression performance as compared with P-pictures, their generation requires greater computational complexity and memory usage, and they introduce additional delays. This may not be a problem for non-real time applications such as video streaming but may cause problems in real-time applications such as video-conferencing.

A compressed video clip typically consists of a sequence of pictures, which can be roughly categorised into temporally independent INTRA pictures and temporally differentially coded INTER pictures. Since the compression efficiency in INTRA pictures is normally lower than in INTER pictures, INTRA pictures are used sparingly, especially in low bit-rate applications.

A video sequence may consist of a number of scenes or shots. The picture contents may be remarkably different

2

from one scene to another, and therefore the first picture of a scene is typically INTRA-coded. There are frequent scene changes in television and film material, whereas scene cuts are relatively rare in video conferencing. In addition, INTRA pictures are typically inserted to stop temporal propagation of transmission errors in a reconstructed video signal and to provide random access points to a video bit-stream.

Compressed video is easily corrupted by transmission errors, mainly for two reasons. Firstly, due to utilisation of temporal predictive differential coding (INTER frames), an error is propagated both spatially and temporally. In practice this means that, once an error occurs, it is easily visible to the human eye for a relatively long time. Especially susceptible are transmissions at low bit-rates where there are only a few INTRA-coded frames, so temporal error propagation is not stopped for some time. Secondly, the use of variable length codes increases the susceptibility to errors. When a bit error alters the codeword, the decoder will lose codeword synchronisation and also decode subsequent error-free codewords (comprising several bits) incorrectly until the next synchronisation (or start) code. A synchronisation code is a bit pattern which cannot be generated from any legal combination of other codewords and such codes are added to the bit stream at intervals to enable re-synchronisation. In addition, errors occur when data is lost during transmission. For example, in video applications using the unreliable UDP transport protocol in IP networks, network elements may discard parts of the encoded video bit-stream.

There are many ways for the receiver to address the corruption introduced in the transmission path. In general, on receipt of a signal, transmission errors are first detected and then corrected or concealed by the receiver. Error correction refers to the process of recovering the erroneous data perfectly as if no errors had been introduced in the first place. Error concealment refers to the process of concealing the effects of transmission errors so that they are hardly visible in the reconstructed video sequence. Typically some amount of redundancy is added by the source or transport coding in order to help error detection, correction and concealment. Error concealment techniques can be roughly classified into three categories: forward error concealment, error concealment by post-processing and interactive error concealment. The term "forward error concealment" refers to those techniques in which the transmitter side adds redundancy to the transmitted data to enhance the error resilience of the encoded data. Error concealment by post-processing refers to operations at the decoder in response to characteristics of the received signals. These methods estimate the correct representation of erroneously received data. In interactive error concealment, the transmitter and receiver co-operate in order to minimise the effect of transmission errors. These methods heavily utilise feedback information provided by the receiver. Error concealment by post-processing can also be referred to as passive error concealment whereas the other two categories represent forms of active error concealment.

There are numerous known concealment algorithms, a review of which is given by Y. Wang and Q.-F. Zhu in "Error Control and Concealment for Video Communication: A Review", Proceedings of the IEEE, Vol. 86, No. 5, May 1998, pp. 974-997 and an article by P. Salama, N. B. Shroff, and E. J. Delp, "Error Concealment in Encoded Video," submitted to IEEE Journal on Selected Areas in Communications.

Current video coding standards define a syntax for a self-sufficient video bit-stream. The most popular standards at the time of writing are ITU-T Recommendation H.263,

"Video coding for low bit rate communication", February 1998; ISO/IEC 14496-2, "Generic Coding of Audio-Visual Objects. Part 2: Visual", 1999 (known as MPEG-4); and ITU-T Recommendation H.262 (ISO/IEC 13818-2) (known as MPEG-2). These standards define a hierarchy for bit-streams and correspondingly for image sequences and images.

In H.263, the syntax has a hierarchical structure with four layers: picture, picture segment, macroblock, and block layer. The picture layer data contain parameters affecting the whole picture area and the decoding of the picture data. Most of this data is arranged in a so-called picture header.

The picture segment layer can either be a group of blocks layer or a slice layer. By default, each picture is divided into groups of blocks. A group of blocks (GOB) typically comprises 16 successive pixel lines. Data for each GOB consists of an optional GOB header followed by data for macroblocks. If the optional slice structured mode is used, each picture is divided into slices instead of GOBs. A slice contains a number of successive macroblocks in scan-order. Data for each slice consists of a slice header followed by data for the macroblocks.

Each GOB or slice is divided into macroblocks. A macroblock relates to 16x16 pixels (or 2x2 blocks) of luminance and the spatially corresponding 8x8 pixels (or block) of chrominance components. A block relates to 8x8 pixels of luminance or chrominance.

Block layer data consists of uniformly quantised discrete cosine transform coefficients, which are scanned in zigzag order, processed with a run-length encoder and coded with variable length codes. MPEG-2 and MPEG-4 layer hierarchies resemble the one in H.263.

By default these standards generally use the temporally previous reference picture (I or P) (also known as an anchor picture) as a reference for motion compensation. This piece of information is not transmitted, i.e., the bit-stream does not include information identifying the reference picture. Consequently, decoders have no means to detect if a reference picture is lost. Although many transport coders place video data into packets and associate a sequence number with the packets, these sequence numbers are not related to the video bit-stream. For example, a section of video bit-stream may contain P-picture P1, B-picture B2, P-picture P3, and P-picture P4, captured (and to be displayed) in this order. However, this section would be compressed, transmitted, and decoded in the following order: P1, P3, B2, P4 since B2 requires both P1 and P3 before it can be encoded or decoded.

Assuming that there is one picture per packet, that each packet contains a sequence number and that the packet carrying B2 is lost, the receiver can detect this packet loss from the packet sequence numbers. However, the receiver has no means to detect if it has lost a motion compensation reference picture for P4 or if it has lost a B-picture, in which case it could continue decoding normally.

The decoder therefore usually sends an INTRA request to the transmitter and freezes the picture on the display. However the transmitter may not be about to respond to this request. For instance in a non-real-time video streaming application, the transmitter cannot respond to an INTRA request from a decoder. Therefore the decoder freezes the picture until the next INTRA frame is received. In a real-time application such as video-conferencing, the transmitter may not be able to respond. For instance, in a multi-party conference, the encoder may not be able to respond to individual requests. Again the decoder freezes the picture until an INTRA frame is output by the transmitter.

SUMMARY OF THE INVENTION

According to a first aspect of the invention there is provided a method of encoding a video signal representing a sequence of pictures, the method employing both non-temporal prediction and temporal prediction, wherein the method comprises, for each picture that forms a reference picture for the temporal prediction of another picture, associating with each such picture an indicator indicating the temporal order of the reference picture in the encoded video signal relative to the other reference pictures in the encoded video signal.

Thus each reference picture (e.g. I-frames and P-frames) is associated with a sequence number. Preferably the indicator is incremented each time a reference picture is encoded. Most advantageously the indicator is incremented by one each time a reference picture is encoded. Thus the indicator is incremented by one from the previous reference picture.

If multi-layer coding is used, preferably this indicator is incremented by one from the previous reference picture in the same enhancement layer.

Including this indicator means that a decoder is capable of determining whether a reference picture has been lost and to take appropriate action, if available. This is the case even if the transport protocol does not include sequence information about the packets being transmitted or the transmitter uses a varying encapsulation strategy. For example, if the transmitter encapsulates a varying number of GOBs in one packet, receivers cannot reliably know how many GOBs or entire pictures were lost even if they could detect packet losses from packet sequence numbers.

The invention also enables a decoder to differentiate B picture losses from reference picture losses. Consequently, decoders can continue decoding after a B picture loss instead of waiting for the next INTRA picture.

In addition a decoder may continue decoding lower enhancement layers if a reference picture from a higher enhancement layer is lost.

The reference picture order number may be in respect of the whole picture or part of a picture. In the former case, typically the reference picture order number is included in a picture header. In a preferred implementation of the invention, the video signal is encoded according to the H.263 standard and the indicator is included in the Supplemental Enhancement Information. Where the RPON is in respect of part of a picture the reference picture order number may be included in the picture segment headers or macroblock headers of the encoded picture.

In accordance with a second aspect of the invention there is provided a method of decoding an encoded video signal representing a sequence of pictures, the method comprising receiving an encoded video signal, decoding each received picture, examining for each picture to be decoded that forms a reference picture for another picture an indicator representing the temporal order of a reference frame and, when the indicator does not follow consecutively from an immediately preceding decoded reference frame, detecting a lost reference frame.

Preferably the decoder sends a request to a transmitter to encode a picture in a non-temporal manner when the indicator does not follow consecutively from an immediately preceding decoded reference frame.

In accordance with a third aspect of the invention there is provided an encoded video signal wherein for each picture that forms a reference picture for the temporal prediction of

5

another picture, an indicator is associated with each such reference picture indicating the temporal order of the reference pictures in the encoded video stream.

In accordance with a fourth aspect of the invention there is provided a video encoder comprising an input for receiving a video signal representing a sequence of pictures and for generating encoded pictures, said encoder being arranged to employ both non-temporal prediction and temporal prediction, wherein the encoder is arranged, for each picture that forms a reference picture for the temporal prediction of another picture, to associate with each reference picture an indicator indicating the temporal order of the reference picture in the encoded video signal relative to other reference pictures in the encoded video signal.

Preferably the indicator is incremented each time a reference picture is encoded.

In accordance with a fifth aspect of the invention there is provided a video decoder comprising an input for receiving an encoded video signal representing a sequence of pictures, a decoder for decoding each received picture, the decoder being arranged to examine for each picture to be decoded that forms a reference picture for another picture an indicator representing the temporal order of a reference frame and, when the indicator does not follow consecutively from an immediately preceding decoded reference frame, to detect a lost reference frame.

The invention also relates to a portable radio communications device including an encoder and/or a decoder as described.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will now be described, by way of example only, with reference to the accompanying drawings, in which:

FIG. 1 shows a multimedia mobile communications system;

FIG. 2 shows an example of the multimedia components of a multimedia terminal;

FIG. 3 shows an example of a video codec;

FIG. 4 illustrates the operation of a first implementation of a video encoder according to a first embodiment of the invention;

FIG. 5 illustrates the operation of a second implementation of a video encoder according to a first embodiment of the invention;

FIG. 6 shows the syntax of a bit stream as known according to H.263;

FIG. 7 shows a first example of a bit stream output by an encoder according to the invention;

FIG. 8 shows a second example of a bit stream output by an encoder according to the invention;

FIG. 9 shows a third example of a bit stream output by an encoder according to the invention;

FIG. 10 illustrates enhancement layers used in video coding for SNR scalability; and

FIG. 11 illustrates enhancement layers used in video coding for spatial scalability.

DETAILED DESCRIPTION OF THE INVENTION

FIG. 1 shows a typical multimedia mobile communications system. A first multimedia mobile terminal 1 communicates with a second multimedia mobile terminal 2 via a

6

radio link 3 to a mobile communications network 4. Control data is sent between the two terminals 1,2 as well as the multimedia data.

FIG. 2 shows the typical multimedia components of a terminal 1. The terminal comprises a video codec 10, an audio codec 20, a data protocol manager 30, a control manager 40, a multiplexer/demultiplexer 50 and a modem 60 (if the required). The video codec 10 receives signals for coding from a video capture device of the terminal (not shown) (e.g. a camera) and receives signals for decoding from a remote terminal 2 for display by the terminal 1 on a display 70. The audio codec 20 receives signals for coding from the microphone (not shown) of the terminal 1 and receive signals for decoding from a remote terminal 2 for reproduction by a speaker (not shown) of the terminal 1.

The control manager 40 controls the operation of the video codec 10, the audio codec 20 and the data protocol manager 30. However, since the invention is concerned with the operation of the video codec 10, no further discussion of the audio codec 20 and protocol manager 30 will be provided.

FIG. 3 shows an example of a video codec 10 according to the invention. The video codec comprises an encoder part 100 and a decoder part 200. The encoder part 100 comprises an input 101 for receiving a video signal from a camera or video source (not shown) of the terminal 1. A switch 102 switches the encoder between an INTRA-mode of coding and an INTER-mode.

In INTRA-mode, the video signal from the input 101 is transformed into DCT coefficients by a DCT transformer 103. The DCT coefficients are then passed to a quantiser 104 that quantises the coefficients. Both the switch 102 and the quantiser 104 are controlled by an encoding control manager 105 of the video codec, which also receives feedback control from the receiving terminal 2 by means of the control manager 40.

In INTER mode, the switch 102 is operated to accept from a subtractor 106 the difference between the signal from the input 101 and a previous picture which is stored in a picture store 107. The difference data output from the subtractor 106 represents the prediction error between the current picture and the previous picture stored in the picture store 107. The data in the picture store 107 is generated by passing the data output by the quantiser through an inverse quantiser 108 and applying an inverse DCT transform 109 to the inverse-quantised data. The resulting data is added to the contents of the picture store 107 by adder 110. A motion estimator 111 may generate motion compensation data from the data in the picture store 107 in a conventional manner.

The encoding control manager 105 decides whether to apply INTRA or INTER coding or whether to code the frame at all on the basis of either the output of the subtractor 106 or in response to feedback control data received a receiving decoder. When not responding to feedback control data, the encoder typically encodes a frame as an INTRA-frame either only at the start of coding (all other frames being P-frames), or at regular periods e.g. every 5s, or when the output of the subtractor exceeds a threshold i.e. when the current picture and that stored in the picture store 107 are too dissimilar. The encoder may also be programmed to encode frames in a particular regular sequence e.g. I B B P B B P B B P B B P B B I B B P etc. In addition the encoding control manager may decide not to code a received frame at all. This happens when the similarity between the current frame and the reference frame is so high that the encoder decides not to encode the current frame. The encoding control manager operates the switch accordingly.

7

The video codec outputs the quantised DCT coefficients **112a**, the quantising index **112b** (i.e. the details of the quantiser used), an INTRA/INTER flag **112c** to indicate the mode of coding performed (I or P/B), a transmit flag **112d** to indicate the number of the frame being coded and the motion vectors **112e** for the picture being coded. These are multiplexed together by the multiplexer **50** together with other multimedia signals.

The decoder part **200** of the video codec **10** comprises an inverse quantiser **120**, an inverse DCT transformer **121**, a motion compensator **122**, a picture store **123** and a controller **124**. The controller **124** receives video codec control signals demultiplexed from the encoded multimedia stream by the demultiplexer **50**. In practice the controller **105** of the encoder and the controller **124** of the decoder may be the same processor.

The operation of an encoder according to the invention will now be described. The video codec **10** receives a video signal to be encoded. The encoder **100** of the video codec encodes the video signal by performing DCT transformation, quantisation and motion compensation. The decoded video data is then output to the multiplexer **50**. The multiplexer **50** multiplexes the video data from the video codec **10** and control data from the control manager **40** (as well as other signals as appropriate) into a multimedia signal. The terminal **1** outputs this multimedia signal to the receiving terminal **2** via the modem **60** (if required).

In a first embodiment of the invention, each time the encoder encodes a frame which may form the reference frame for a subsequent frame, the encoding control manager **105** associates with the frame a so-called Reference Picture Order Number (RPON). For example, a RPON is associated with every I or P frame of a video signal but not with a B-frame. The RPON value is incremented each time a successive reference picture is encoded, preferably by 1.

The encoding control manager **105** outputs the RPON codeword on output **112f** which indicates the Reference Picture Order Number associated with the encoded frame. This is multiplexed into the video bitstream by a multiplexer.

FIG. **4** illustrates the operation of the encoder. In this embodiment, the encoder is arranged to output an I-frame when the similarity between the frame being coded and the reference frame is less than a first threshold i.e. when the output from the subtractor **106** is greater than a first threshold. Otherwise the encoder outputs P-frames. The first line of FIG. **4** represents the frames of data received from a capture input device and input to the video encoder on input **101**. The second line of FIG. **4** represents those frames of the input signal that the encoder decides to encode and the coding mode used to encode each frame. As mentioned above some, the encoding control manager may decide that a frame is not to be coded: this is exemplified in FIG. **4** by the fact that frames **2**, **3** and **11** are not coded.

Frame **1** is coded in INTRA-mode; frame **4** is encoded as a P-frame with reference to frame **1**; frame **5** is encoded as a P-frame with reference to frame **4**; frame **6** is encoded as a P-frame with reference to frame **5**; frame **7** is encoded as a P-frame with reference to frame **6**; frame **8** is encoded as an I-frame; frame **9** is encoded as a P-frame with reference to frame **8**; frame **10** is encoded as a P-frame with reference to frame **9**; frame **12** is encoded as a P-frame with reference to frame **10**.

In this embodiment all (but the last) of the encoded frames act as the reference frame for a later frame. Thus a RPON is associated with all of the frames to be coded, as shown in the third line of FIG. **4**. As can be seen, the RPON is incremented by 1 each time.

8

The fourth line of FIG. **4** shows the Temporal Reference (TR) of the encoded frame. This is a field included in H.263 and the value of TR is formed by incrementing its value in the temporally previous reference picture header by one plus the number of skipped or non-reference pictures since the previously transmitted one. Thus in the example shown in FIG. **4** the TR shown for each frame is the same as the original number in the original signal input to **102**.

FIG. **5** shows a second embodiment of an encoder according to the invention. In this embodiment, the encoder is arranged to code the frames according to the regular sequence I B B P B B P B B P B B P B I B B P. The first line of FIG. **5** shows the input frames and the second line shows the coded frames and their coding mode, I, P or B.

The frames are received from a video capture device in the order **1,2,3,4,5,6** etc. and are displayed in this order i.e. the decoded frames are displayed in the order **I1, B2, B3, P4, B5, B6, P7** etc. However the video bit stream is compressed, transmitted and decoded in the following order **I1, P4, B2, B3, P7, B5, B6** etc. This is because each B-frame requires preceding and succeeding reference frames before they can be encoded/decoded i.e. frame **B2** requires frame **I1** and **P4** to be encoded/decoded before frame **B2** can be encoded/decoded.

As explained previously, B-frames are inserted between anchor picture pairs of I- and/or P-frames and are predicted from either one or both of these anchor pictures. Thus in the illustration given in FIG. **5**, Frame **1** is coded in INTRA-mode; frame **4** is encoded as a B-frame with reference to frame **1** and/or **6**; frame **5** is encoded as a B-frame with reference to frame **1** and/or **6**; frame **6** is encoded as a P-frame with reference to frame **1**; frame **7** is encoded as a B-frame with reference to frame **6** and/or **9**; frame **8** is encoded as an B-frame with reference to frame **6** and/or **9**; frame **9** is encoded as a P-frame with reference to frame **6**; frame **10** is encoded as a B-frame with reference to frame **9** and/or **13** (not shown); frame **12** is encoded as a B-frame with reference to frame **9** and/or **13** and so on.

In this embodiment each I-frame and P-frame of the encoded sequence acts as a reference frame for another frame. However a B-frame does not act as a reference picture for any other frame. Thus a RPON is associated with all of the I-frames and P-frames, as shown in the third line of FIG. **5**. As can be seen, the RPON is incremented by 1 each time. Thus frame **1** (an I-frame) has a RPON of 1, frame **4** (a P-frame) has a RPON of 2 and frame **9** (a P-frame) has a RPON of 3.

The fourth line of FIG. **5** shows the Temporal Reference (TR) of the encoded frame. As in the example shown in FIG. **4**, the TR shown for each frame is the same as the order of occurrence in the original signal input to **10**.

Considering the terminal **1** as receiving coded video data from terminal **2**, the operation of the video codec **10** will now be described with reference to its decoding role. The terminal **1** receives a multimedia signal from the transmitting terminal **2**. The demultiplexer **50** demultiplexes the multimedia signal and passes the video data to the video codec **10** and the control data to the control manager **40**. The decoder **200** of the video codec decodes the encoded video data by inverse quantising, inverse DCT transforming and motion compensating the data. The controller **124** of the decoder checks the integrity of the received data and, if an error is detected, attempts to conceal the error in a manner to be described below. The decoded, corrected and concealed video data is then output for reproduction on a display **70** of the receiving terminal **1**.

Errors in video data may occur at the picture level, the GOB level or the macroblock level. Error checking may be carried out at any or all of these levels.

Considering first the signal as shown in FIG. 4, when a decoder according to the invention receives this signal each frame of the signal is decoded in a conventional manner and then displayed on a display means. The decoded frame may be error corrected and error concealed in a conventional manner. Each time a frame is decoded, the decoder examines the TR field to determine when the frame is to be displayed. If the TRs are not consecutive (e.g. the decoder receives a frame with TR=1 and then a frame with TR=4) the decoder holds the frame 1 on the display for 3 times the usual frame period, as is conventional. The decoder also examines the RPON of the received frames. In the case shown in FIG. 4 the decoder receives frame 1 and sees that this frame has a RPON=1; the decoder then receives a frame with TR=4 and RPON=2. The decoder compares the RPON of the currently received frame with the RPON of the previously received frame and calculates the difference between the RPON values. In this case the difference is 1 and the decoder therefore knows that no reference pictures have been lost between the current frame and the previous decoded reference frame. The decoder therefore continues to decode the signal in a conventional manner.

Let us now assume that the decoder is unable to reconstruct frame 5 (this could be due to the data being greatly corrupted or being lost altogether) and the next frame received and decoded by the decoder is frame 6. The decoder compares the RPON of the currently received frame (frame 6) with the RPON of the previously received and decoded reference frame (frame 4) and calculates the difference between the RPON values. In this case the difference is 2 and the decoder therefore knows that a reference picture has been lost between transmission of the current frame and that of the previous frame. If the decoder has the facility to send control feedback data to the transmitting video encoder the decoder can send a request to the transmitting video encoder to encode a frame as an INTRA-frame and so stop the temporal error propagation that would result from frame 6 being decoded with reference to frame 4.

Considering now the signal as shown in FIG. 5, when a decoder according to the invention receives this signal each frame of the signal is decoded in a conventional manner and then displayed on a display means. The decoded frame may be error corrected and error concealed in a conventional manner. Each time a frame is decoded, the decoder examines the TR field to determine when the frame is to be displayed. The decoder also examines the RPON of the received frames.

In the case shown in FIG. 5 the decoder receives frame 1 and sees that this frame has a RPON=1. The decoder decodes this frame in a conventional INTRA-mode manner. The next frame received by the decoder is then frame 6, with TR=6 and RPON=2. The decoder compares the RPON of the currently received frame (frame 6) with the RPON of the previously received and decoded reference frame (frame 1) and calculates the difference between the RPON. In this case the difference is 1 and the decoder therefore knows that no reference pictures have been lost between transmission of the current frame and that of the previous decoded reference frame. The decoder then decodes frame 6 with reference to frame 1.

The decoder then receives a frame with TR=4 and no RPON. In this case the decoder makes no further use of the RPON and decodes frame 4 with reference to decoded frames 1 and 6.

Let us now assume that the decoder is unable to reconstruct frame 5 (this could be due to the data being greatly corrupted or being lost altogether). The fact that B-frame 5 has been lost is of no consequence to the decoder as the B-frame does not form a reference picture for any other frame and thus its loss will not introduce any temporal error propagation.

The next frame to be received is frame 9. However, let us now assume that the decoder is unable to reconstruct frame 9, which is a P-frame (this could be due to the data being greatly corrupted or being lost altogether). The decoder may therefore be unable to decode successfully any of frames 7, 8, 10 or 12 since these may all be predicted, in part at least, with reference to frame 9. Typically, in this situation, the decoder will freeze the displayed picture.

The next frame received and decoded by the decoder is frame 13. The decoder compares the RPON of the currently received reference frame (frame 13) with the RPON of the previously received and decoded reference frame (frame 6) and calculates the difference between the RPON. In this case the difference is 2 and the decoder therefore knows that a reference picture has been lost between the current frame and the previous decoded reference frame. If the decoder has the facility to send control feedback data to the transmitting video encoder the decoder can send a request to the transmitting video encoder to encode a frame as an INTRA-frame and so stop the temporal error propagation that would result from frame 13 being decoded with reference to frame 6.

How the reference picture order number may be included in the encoded signal will now be addressed with reference to the H.263 video coding standard.

FIG. 6 shows the syntax of a bit stream as known according to H.263. The following implementations describe the GOB format but it will be clear to a skilled person that the invention may also be implemented in the slice format.

As mentioned already, the bit stream has four layers: the picture layer, picture segment layer, macroblock layer and block layer. The picture layer comprises a picture header followed by data for the Group of Blocks, eventually followed by any optional end-of-sequence code and stuffing bits.

The prior art H.263 bit stream is formatted as shown in FIG. 6. A descriptor for each part is given below:

PSC	The picture start code (PSC) indicates the start of the picture
TR	The Temporal Reference (TR) is formed by incrementing its value in the temporally previous reference picture header by one plus the number of skipped or non-referenced pictures since the previously transmitted one
PTYPE	Amongst other things, PTYPE includes details of the picture coding type i.e. INTRA or INTER
PQUANT	A codeword that indicates the quantiser to be used for the picture until updated by any subsequent quantiser information
CPM	A codeword that signals the use of optional continuous presence multipoint and video multiplex (CPM) mode
PSBI	Picture Sub-Bit stream Indicator-only present if CPM is set
TR _B	Present if the frame is a bi-directionally predicted frame (known as a PB-frame)
DBQUANT	Present if a bi-directional frame
PEI	This relates to extra insertion information and is set to "1" to indicate the presence of the following optional data fields PSUPP and PEI. PSUPP and PEI are together known as Supplemental Enhancement Information, which is further defined in Annex L of H263.

-continued

GOBS	Is the data for the group of blocks for the current picture
ESTF	A stuffing codeword provided to attain byte alignment before EOS
EOS	A codeword indicating the end of the data sequence for the picture
PSTUF	A stuffing codeword to allow for byte alignment of the next picture start code PSC

The structure as shown in FIG. 4 does not include the optional PLUSTYPE data field. PSBI is only present if indicated by CPM. TRB and DBQUANT are only present if PTYPE indicates use of a so-called PB frame mode (unless the PLUSTYPE field is present and the use of DBQUANT is indicated therein). These issues are addressed in more detail in the H.263 specification.

The following paragraphs outline possible implementations of the bit-stream output by an encoder according to the first aspect of the invention.

The reference picture order number may be incorporated into a H.263 bit stream as follows. FIG. 7 shows an example of a bit stream output by an encoder according to the first implementation of the invention. As shown in FIG. 7, the bit stream includes a further codeword RPON which is a codeword indicating the reference picture order number. This is inserted by an encoder according to the invention, as described above.

Alternatively, the reference picture order number may be included in the Supplemental Enhancement Information PSUPP (see Annex L of H.263 and FIG. 4). The supplemental information may be present in the bit stream even though the decoder may not be capable of providing the enhanced capability to use it, or even to properly interpret it. Simply discarding the supplemental information is allowable by decoders unless a requirement to provide the requested capability has been negotiated by the transmitter and receiver.

If PEI is set to "1", then 9 bits follow consisting of 8 bits of data (PSUPP) and then another PEI bit to indicate if a further 9 bits follow and so on.

The PSUPP data consists of a 4-bit function type indication FTYPE, followed by a 4-bit parameter data size specification DSIZE followed by DSIZE octets of function parameter data, optionally followed by another FTYPE and so on. It is known to use this PSUPP codeword to signal various situations such as: to indicate a full-picture or partial-picture freeze or freeze-release request with or without resizing; to tag particular pictures or sequences of pictures within the video stream for external use; or to convey chroma key information for video compositing.

To implement the invention using the Supplemental Enhancement Information, a further FTYPE is defined as Reference Picture Order Number.

FIG. 8 illustrates the example where a parameter RPON is included in the SEI of the picture header. The FTYPE is defined as RPON. The DSIZE specifies the size of the parameter and the following octet is the parameter data i.e. the value of RPON. From this value a receiving decoder can determine whether a reference picture has been lost.

Alternatively, the information may be contained in the additional Supplemental Enhancement Information as specified in a "Draft of new Annex W: Additional Supplementary Enhancement Information Specification" P. Ning and S. Wenger, ITU-T Study Group 16 Question 15 Document Q15-I58, November 1999.

In this draft proposal, FTYPE 14 is defined as "Picture Message". When this FTYPE is set, the picture message function indicates the presence of one or more octets representing message data. The first octet of the message data is a message header with the structure shown in FIG. 9 i.e. CONT, EBIT and MTYPE. DSIZE is equal to the number of octets in the message data corresponding to a picture message function, including the first octet message header.

The continuation field CONT, if equal to 1, indicates that the message data associated with the picture message is part of the same logical message as the message data associated with the next picture message function. The End Bit Position field EBIT specifies the number of least significant bits that shall be ignored in the last message octet. Further details of these fields can be found in the draft of Annex W referred to above.

The field MTYPE indicates the type of message. Various types of message are suggested in the draft of Annex W. According to the invention one type e.g. MTYPE 12 is defined as RPON or Picture Number. The message contains two data bytes that carry a 10-bit Picture Number. Consequently, DSIZE shall be 3, CONT shall be 0, and EBIT shall be 6. Picture Number shall be incremented by 1 for each coded and transmitted I or P picture or PB or Improved PB frame, in a 10-bit modulo operation. For EI and EP pictures, Picture Number shall be incremented for each EI or EP picture within the same scalability enhancement layer. For B pictures, Picture Number shall be incremented relative to the value in the most recent non-B picture in the reference layer of the B picture which precedes the B picture in bitstream order (a picture which is temporally subsequent to the B picture). If adjacent pictures in the same enhancement layer have the same temporal reference, and if the reference picture selection mode (see Annex N) is in use, the decoder shall regard this occurrence as an indication that redundant copies have been sent of approximately the same pictured scene content, and all of these pictures shall share the same Picture Number. If the difference (modulo 1024) of the Picture Numbers of two consecutively received non-B pictures in the same enhancement layer is not 1, and if the pictures do not represent approximately the same pictured scene content as described above, a loss of pictures or corruption of data may be inferred by the decoder. The value of RPON is defined in the octet following the message header.

In a specific example, this message contains one data byte, i.e., DSIZE is 2, CONT is 0, and EBIT is 0.

The Reference Picture Order Number is incremented by one from the corresponding number of the previous coded reference picture. The least significant 8-bits of the result of the incrementation is placed in the data byte associated with this message.

The invention may also be implemented in accordance with Annex U of H.263.

The above description has made reference to encoded video streams in which bi-directionally predicted pictures (B-pictures) are encoded. As mentioned earlier, B-pictures are never used as reference pictures. Since they can be discarded without impacting the picture quality of future pictures, they provide temporal scalability. Scalability allows for the decoding of a compressed video sequence at more than one quality level. In other words, a scalable multimedia clip can be compressed so that it can be streamed over channels with different data rates and still be decoded and played back in real-time.

Thus the video stream may be decoded in different ways by differing decoders. For instance, a decoder can decide

only to decode the I- and P-pictures of a signal, if this is the maximum rate of decoding that the decoder can attain. However if a decoder has the capacity, it can also decode the B-pictures and hence increase the picture display rate. Thus the perceived picture quality of the displayed picture will be enhanced over a decoder that only decodes the I- and P-pictures.

Scalable multimedia is typically ordered so that there are hierarchical layers of data. A base layer contains a basic representation of the multimedia clip whereas enhancement layers contain refinement data on top of underlying layers. Consequently, the enhancement layers improve the quality of the clip.

Scalability is a desirable property for heterogeneous and error prone environments. This property is desirable in order to counter limitations such as constraints on bit rate, display resolution, network throughput, and decoder complexity.

Scalability can be used to improve error resilience in a transport system where layered coding is combined with transport prioritisation. The term transport prioritisation here refers to various mechanisms to provide different qualities of service in transport, including unequal error protection, to provide different channels having different error/loss rates. Depending on their nature, data are assigned differently. For example, the base layer may be delivered through a channel with a high degree of error protection, and the enhancement layers may be transmitted through more error-prone channels.

Generally, scalable multimedia coding suffers from a worse compression efficiency than non-scalable coding. In other words, a multimedia clip encoded as a scalable multimedia clip with enhancement layers requires greater bandwidth than if it had been coded as a non-scalable single-layer clip with equal quality. However, exceptions to this general rule exist, for example the temporally scalable B-frames in video compression.

The invention may be applied to other scalable video compression systems. For instance, in H.263 Annex O, two other forms of scalability are defined: signal-to-noise (SNR) scalability and spatial scalability. Spatial scalability and SNR scalability are closely related, the only difference being the increased spatial resolution provided by spatial scalability. An example of SNR scalable pictures is shown in FIG. 10. SNR scalability implies the creation of multi-rate bit streams. It allows for the recovery of coding errors, or differences between an original picture and its reconstruction. This is achieved by using a finer quantiser to encode the difference picture in an enhancement layer. This additional information increases the SNR of the overall reproduced picture.

Spatial scalability allows for the creation of multi-resolution bit streams to meet varying display requirements and/or constraints. A spatially scalable structure is illustrated in FIG. 11. It is essentially the same as in SNR scalability except that a spatial enhancement layer attempts to recover the coding loss between an up-sampled version of the reconstructed reference layer picture and a higher resolution version of the original picture. For example, if the reference layer has a quarter common intermediate format (OCIF) resolution, and the enhancement layer has a common intermediate format (CIF) resolution, the reference layer picture must be scaled accordingly such that the enhancement layer picture can be predicted from it. The OCIF standard allows the resolution to be increased by a factor of two in the vertical direction only, horizontal direction only, or both the vertical and horizontal directions for a single enhancement

layer. There can be multiple enhancement layers, each increasing the picture resolution over that of the previous layer. The interpolation filters used to up-sample the reference layer picture are explicitly defined in the H.263 standard. Aside from the up-sampling process from the reference to the enhancement layer, the processing and syntax of a spatially scaled picture are identical to those of an SNR scaled picture.

In either SNR or spatial scalability, the enhancement layer pictures are referred to as EI- or EP-pictures. If the enhancement layer picture is upwardly predicted from a picture in the reference layer, then the enhancement layer picture is referred to as an Enhancement-I (EI) picture. In this type of scalability, the reference layer means the layer "below" the current enhancement layer. In some cases, when reference layer pictures are poorly predicted, over-coding of static parts of the picture can occur in the enhancement layer, causing an unnecessarily excessive bit rate. To avoid this problem, forward prediction is permitted in the enhancement layer. A picture that can be predicted in the forward direction from a previous enhancement layer picture or, alternatively, upwardly predicted from the reference layer picture is referred to as an Enhancement-P (EP) picture. Note that computing the average of the upwardly and forwardly predicted pictures can provide bi-directional prediction for EP-pictures. For both EI- and EP-pictures, upward prediction from the reference layer picture implies that no motion vectors are required. In the case of forward prediction for EP-pictures, motion vectors are required.

According to the invention, if the encoder is capable of multi-layer coding (for example as discussed in Annex O of H.263) the reference pictures of each layer are given consecutive Reference Picture Order Numbers. These may be associated with the enhancement layer number (ELNUM) of the current picture. The Reference Picture Order Number is incremented by one from the corresponding number of the previous coded reference picture in the same enhancement layer.

As shown in FIGS. 10 and 11, the pictures of the enhancement layer may be predicted from a preceding picture of the enhancement layer and/or from the equivalent I- or P-picture of the base layer. The enhancement layer may not be predicted from a B-picture in the reference layer.

If adjacent pictures in the same enhancement layer have the same temporal reference, and if Annex N or Annex U of H.263 is in use, the decoder preferably regards this occurrence as an indication that redundant copies have been sent of approximately the same pictured scene content, and all of these pictures then share the same RPON.

A decoder according to the invention, on receipt of a multi-layer signal as described above, attempts to decode the signal in a conventional manner. In each layer, each time a reference picture is decoded, the decoder examines the RPON of the decoded picture. If the decoder determines that a reference picture has been lost from an enhancement layer, the decoder ceases to display pictures from the enhancement layer until an EI-picture is received. The decoder continues to decode the base layer as described earlier.

The invention is not intended to be limited to the video coding protocols discussed above: these are intended to be merely exemplary. The invention is applicable to any video coding protocol in which temporal prediction may be used. The addition of the information as discussed above allows a receiving decoder to determine that a reference picture has been lost and to take appropriate action.

15

What is claimed is:

1. A method of encoding a video signal representing a sequence of pictures to form an encoded video signal comprising temporally independent INTRA pictures and temporally predicted pictures, wherein the INTRA pictures and at least some of the temporally predicted pictures are used to form reference pictures for the temporal prediction of other pictures in the video sequence, comprising indicating an encoding order of those pictures used to form reference pictures in the encoded video signal with a sequence indicator having an independent numbering scheme, such that consecutive pictures used to form reference pictures in encoding order are assigned sequence indicator values that differ with respect to each other by a predetermined amount independent of the number of non-reference pictures encoded between successive reference pictures.

2. A method according to claim 1, wherein said predetermined amount is one.

3. A method according to claim 1, wherein the sequence indicator is included in a picture header.

4. A method according to claim 3, wherein the video signal is encoded according to the H.263 video coding standard and the sequence indicator is included in the Supplemental Enhancement Information of a bit stream of the H.263 video coding standard.

5. A method of decoding an encoded video signal representing a sequence of pictures to form a decoded video signal, the method comprising receiving an encoded video signal comprising temporally independent INTRA pictures and temporally predicted pictures, wherein the INTRA pictures and at least some of the temporally predicted pictures are used to form reference pictures for the temporal prediction of other pictures, the encoded video signal further comprising a sequence indicator having an independent numbering scheme such that consecutive reference pictures in encoding order are assigned sequence indicator values that differ with respect to each other by a predetermined amount independent of the number of non-reference pictures encoded between successive reference pictures, decoding received encoded pictures, examining each decoded picture that forms a reference picture to identify the sequence indicator value assigned to the reference picture and comparing the sequence indicator values assigned to consecutively decoded reference pictures to detect loss of a reference picture.

6. A method according to claim 5, further comprising sending a request to a transmitter to encode a picture in a non-temporally predicted manner when the sequence indicator value assigned to a particular reference picture does not follow consecutively from that associated with an immediately preceding decoded reference picture.

7. A video encoder comprising an input for receiving a video signal representing a sequence of pictures, the video encoder for generating an encoded video signal comprising temporally independent INTRA pictures and temporally predicted pictures, wherein the INTRA pictures and at least some of the temporally predicted pictures form reference pictures for temporal prediction of other pictures, and the encoder is arranged to indicate an encoding order of the reference pictures in the encoded video signal with a sequence indicator having an independent numbering scheme, such that consecutive reference pictures in encoding order are assigned sequence indicator values that differ with respect to each other by a predetermined amount independent of the number of non-reference pictures encoded between successive reference pictures.

16

8. A video encoder according to claim 7, wherein said predetermined amount is one.

9. A video decoder for decoding an encoded video signal representing a sequence of pictures to form a decoded video signal, the encoded video signal comprising temporally independent INTRA pictures and temporally predicted pictures, wherein the INTRA pictures and at least some of the temporally predicted pictures form reference pictures for the temporal prediction of other pictures, the encoded video signal further comprising a sequence indicator having an independent numbering scheme such that consecutive reference pictures in encoding order are assigned sequence indicator values that differ with respect to each other by a predetermined amount independent of the number of non-reference pictures encoded between successive reference pictures, comprising an input for receiving the encoded video signal and being arranged to decode received encoded pictures, to examine each decoded picture that forms a reference picture to identify the sequence indicator value assigned to the reference picture and to compare the sequence indicator values assigned to consecutively decoded reference pictures to detect loss of a reference picture.

10. A portable radio communications device including an encoder according to claim 7.

11. A method according to claim 1, wherein the sequence indicator is associated with a whole picture.

12. A method according to claim 1, wherein the sequence indicator is associated with part of a picture.

13. A method according to claim 12, wherein the sequence indicator is included in a picture segment header or a macroblock header of an encoded picture.

14. A method according to claim 1, wherein the video signal is scalably encoded and sequence indicators are associated with layers of the scalably encoded video signal.

15. A method according to claim 5, wherein the predetermined amount is one.

16. A method according to claim 5, wherein the sequence indicator is included in a picture header.

17. A method according to claim 5, wherein the video signal is encoded according to the H.263 video coding standard and the sequence indicator is included in the Supplemental Enhancement Information of a bit-stream of the H.263 video coding standard.

18. A method according to claim 5, wherein the sequence indicator is associated with a whole picture.

19. A method according to claim 5, wherein the sequence indicator is associated with part of a picture.

20. A method according to claim 19, wherein the sequence indicator is included in a picture segment header or a macroblock header of an encoded picture.

21. A method according to claim 5, wherein the video signal is scalably encoded and sequence indicators are associated with layers of the scalably encoded video signal.

22. A video encoder according to claim 7, arranged to include the sequence indicator in a picture header.

23. A video encoder according to claim 7, arranged to encode the video signal according to the H.263 video coding standard and to include the sequence indicator in the Supplemental Enhancement Information of a bit stream of the H.263 video coding standard.

24. A video encoder according to claim 7, arranged to associate the sequence indicator with a whole picture.

25. A video encoder according to claim 7, arranged to associate the sequence indicator with part of a picture.

26. A video encoder according to claim 7, arranged to include the sequence indicator in a picture segment header or a macroblock header of an encoded picture.

17

27. A video encoder according to claim 7, arranged to encode the video signal scalably and to associate sequence indicators with layers of the scalably encoded video signal.

28. A video decoder according to claim 9, further arranged to send a request to a transmitter to encode a picture in a non-temporally predicted manner when the sequence indicator value assigned to a particular reference picture does not follow consecutively from that associated with an immediately preceding decoded reference picture.

29. A video decoder according to claim 9, wherein the predetermined amount is one.

30. A video decoder according to claim 9, wherein the sequence indicator is included in a picture header.

31. A video decoder according to claim 9, wherein the video signal is encoded according to the H.263 video coding standard and the sequence indicator is included in the Supplemental Enhancement Information of a bit stream of the H.263 video coding standard.

32. A video decoder according to claim 9, wherein the sequence indicator is associated with a whole picture.

33. A video decoder according to claim 9, wherein the sequence indicator is associated with part of a picture.

34. A video decoder according to claim 33, wherein the sequence indicator is included in a picture segment header or a macroblock header of an encoded picture.

35. A video decoder according to claim 9, wherein the video signal is scalably encoded and sequence indicators are associated with layers of the scalably encoded video signal.

36. A multimedia terminal device including an encoder according to claim 7.

37. An encoded video signal representing a sequence of pictures, comprising temporally independent INTRA pictures and temporally predicted pictures, wherein the INTRA pictures and at least some of the temporally predicted pictures form reference pictures for the temporal prediction of other pictures, the encoded video signal further comprising a sequence indicator having an independent numbering

18

scheme for indicating an encoding order of the reference pictures, such that consecutive reference pictures in encoding order are assigned sequence indicator values that differ with respect to each other by a predetermined amount independent of the number of non-reference pictures encoded between successive reference pictures.

38. An encoded video signal according to claim 37, wherein said predetermined amount is one.

39. An encoded video signal according to claim 37, wherein the sequence indicator is included in a picture header.

40. An encoded video signal according to claim 37, encoded according to the H.263 video coding standard and the sequence indicator is included in the Supplemental Enhancement Information of a bit stream of the H.263 video coding standard.

41. An encoded video signal according to claim 37, wherein the sequence indicator is associated with the whole of a picture.

42. An encoded video signal according to claim 37, wherein the sequence indicator is associated with part of a picture.

43. An encoded video signal according to claim 42, wherein the sequence indicator is included in a picture segment header or a macroblock header of an encoded picture.

44. An encoded video signal according to claim 37, wherein the encoded video signal is scalably encoded and sequence indicators are associated with layers of the scalably encoded video signal.

45. A portable radio communications device including a decoder according to claim 9.

46. A multimedia terminal device including a decoder according to claim 9.

(57) **ABSTRACT**

A method of encoding a video signal representing a sequence of pictures, the method employing both non-temporal prediction and temporal prediction, wherein the method comprises, for each picture that forms a reference picture for the temporal prediction of another picture, associating with each such picture an indicator indicating the temporal order of the reference picture in the encoded video signal relative to the other reference pictures in the encoded video signal.

VIDEO CODING

RELATED APPLICATIONS

This application is a continuation application of application Ser. No. 09/855,640 filed May 15, 2001 now U.S. Pat. No. 6,968,005.

BACKGROUND OF THE INVENTION

This invention related to video coding.

A video sequence consists of a series of still pictures or frames. Video compression methods are based on reducing the redundant and perceptually irrelevant parts of video sequences. The redundancy in video sequences can be categorised into spectral, spatial and temporal redundancy. Spectral redundancy refers to the similarity between the different colour components of the same picture. Spatial redundancy results from the similarity between neighbouring pixels in a picture. Temporal redundancy exists because objects appearing in a previous image are also likely to appear in the current image. Compression can be achieved by taking advantage of this temporal redundancy and predicting the current picture from another picture, termed an anchor or reference picture. Further compression is achieved by generating motion compensation data that describes the motion between the current picture and the previous picture.

However, sufficient compression cannot usually be achieved by only reducing the inherent redundancy of the sequence. Thus, video encoders also try to reduce the quality of those parts of the video sequence which are subjectively less important. In addition, the redundancy of the encoded bit-stream is reduced by means of efficient lossless coding of compression parameters and coefficients. The main technique is to use variable length codes.

Video compression methods typically differentiate between pictures that utilise temporal redundancy reduction and those that do not. Compressed pictures that do not utilise temporal redundancy reduction methods are usually called INTRA or I-frames or I-pictures. Temporally predicted images are usually forwardly predicted from a picture occurring before the current picture and are called INTER or P-frames. In the INTER frame case, the predicted motion-compensated picture is rarely precise enough and therefore a spatially compressed prediction error frame is associated with each INTER frame. INTER pictures may contain INTRA-coded areas.

Many video compression schemes also use temporally bi-directionally predicted frames, which are commonly referred to as B-pictures or B-frames. B-pictures are inserted between anchor picture pairs of I- and/or P-frames and are predicted from either one or both of these anchor pictures. B-pictures normally yield increased compression as compared with forward-predicted pictures. B-pictures are not used as anchor pictures, i.e., other pictures are not predicted from them. Therefore they can be discarded (intentionally or unintentionally) without impacting the picture quality of future pictures. Whilst B-pictures may improve compression performance as compared with P-pictures, their generation requires greater computational complexity and memory usage, and they introduce additional delays. This may not be a problem for non-real time applications such as video streaming but may cause problems in real-time applications such as video-conferencing.

A compressed video clip typically consists of a sequence of pictures, which can be roughly categorised into temporally independent INTRA pictures and temporally differentially

2

coded INTER pictures. Since the compression efficiency in INTRA pictures is normally lower than in INTER pictures, INTRA pictures are used sparingly, especially in low bit-rate applications.

A video sequence may consist of a number of scenes or shots. The picture contents may be remarkably different from one scene to another, and therefore the first picture of a scene is typically INTRA-coded. There are frequent scene changes in television and film material, whereas scene cuts are relatively rare in video conferencing. In addition, INTRA pictures are typically inserted to stop temporal propagation of transmission errors in a reconstructed video signal and to provide random access points to a video bit-stream.

Compressed video is easily corrupted by transmission errors, mainly for two reasons. Firstly, due to utilisation of temporal predictive differential coding (INTER frames), an error is propagated both spatially and temporally. In practice this means that, once an error occurs, it is easily visible to the human eye for a relatively long time. Especially susceptible are transmissions at low bit-rates where there are only a few INTRA-coded frames, so temporal error propagation is not stopped for some time. Secondly, the use of variable length codes increases the susceptibility to errors. When a bit error alters the codeword, the decoder will lose codeword synchronisation and also decode subsequent error-free codewords (comprising several bits) incorrectly until the next synchronisation (or start) code. A synchronisation code is a bit pattern which cannot be generated from any legal combination of other codewords and such codes are added to the bit stream at intervals to enable re-synchronisation. In addition, errors occur when data is lost during transmission. For example, in video applications using the unreliable UDP transport protocol in IP networks, network elements may discard parts of the encoded video bit-stream.

There are many ways for the receiver to address the corruption introduced in the transmission path. In general, on receipt of a signal, transmission errors are first detected and then corrected or concealed by the receiver. Error correction refers to the process of recovering the erroneous data perfectly as if no errors had been introduced in the first place. Error concealment refers to the process of concealing the effects of transmission errors so that they are hardly visible in the reconstructed video sequence. Typically some amount of redundancy is added by the source or transport coding in order to help error detection, correction and concealment. Error concealment techniques can be roughly classified into three categories: forward error concealment, error concealment by post-processing and interactive error concealment. The term "forward error concealment" refers to those techniques in which the transmitter side adds redundancy to the transmitted data to enhance the error resilience of the encoded data. Error concealment by post-processing refers to operations at the decoder in response to characteristics of the received signals. These methods estimate the correct representation of erroneously received data. In interactive error concealment, the transmitter and receiver co-operate in order to minimise the effect of transmission errors. These methods heavily utilise feedback information provided by the receiver. Error concealment by post-processing can also be referred to as passive error concealment whereas the other two categories represent forms of active error concealment.

There are numerous known concealment algorithms, a review of which is given by Y. Wang and Q.-F. Zhu in "Error Control and Concealment for Video Communication: A Review", Proceedings of the IEEE, Vol. 86, No. 5, May 1998, pp. 974-997 and an article by P. Salama, N. B. Shroff, and E.

J. Delp, "Error Concealment in Encoded Video," submitted to IEEE Journal on Selected Areas in Communications.

Current video coding standards define a syntax for a self-sufficient video bit-stream. The most popular standards at the time of writing are ITU-T Recommendation H.263, "Video coding for low bit rate communication", February 1998; ISO/IEC 14496-2, "Generic Coding of Audio-Visual Objects. Part 2: Visual", 1999 (known as MPEG-4); and ITU-T Recommendation H.262 (ISO/IEC 13818-2) (known as MPEG-2). These standards define a hierarchy for bit-streams and correspondingly for image sequences and images.

In H.263, the syntax has a hierarchical structure with four layers: picture, picture segment, macroblock, and block layer. The picture layer data contain parameters affecting the whole picture area and the decoding of the picture data. Most of this data is arranged in a so-called picture header.

The picture segment layer can either be a group of blocks layer or a slice layer. By default, each picture is divided into groups of blocks. A group of blocks (GOB) typically comprises 16 successive pixel lines. Data for each GOB consists of an optional GOB header followed by data for macroblocks. If the optional slice structured mode is used, each picture is divided into slices instead of GOBs. A slice contains a number of successive macroblocks in scan-order. Data for each slice consists of a slice header followed by data for the macroblocks.

Each GOB or slice is divided into macroblocks. A macroblock relates to 16x16 pixels (or 2x2 blocks) of luminance and the spatially corresponding 8x8 pixels (or block) of chrominance components. A block relates to 8x8 pixels of luminance or chrominance.

Block layer data consist of uniformly quantised discrete cosine transform coefficients, which are scanned in zigzag order, processed with a run-length encoder and coded with variable length codes. MPEG-2 and MPEG-4 layer hierarchies resemble the one in H.263.

By default these standards generally use the temporally previous reference picture (I or P) (also known as an anchor picture) as a reference for motion compensation. This piece of information is not transmitted, i.e., the bit-stream does not include information identifying the reference picture. Consequently, decoders have no means to detect if a reference picture is lost. Although many transport coders place video data into packets and associate a sequence number with the packets, these sequence numbers are not related to the video bit-stream. For example, a section of video bit-stream may contain P-picture P1, B-picture B2, P-picture P3, and P-picture P4, captured (and to be displayed) in this order. However, this section would be compressed, transmitted, and decoded in the following order: P1, P3, B2, P4 since B2 requires both P1 and P3 before it can be encoded or decoded. Assuming that there is one picture per packet, that each packet contains a sequence number and that the packet carrying B2 is lost, the receiver can detect this packet loss from the packet sequence numbers. However, the receiver has no means to detect if it has lost a motion compensation reference picture for P4 or if it has lost a B-picture, in which case it could continue decoding normally.

The decoder therefore usually sends an INTRA request to the transmitter and freezes the picture on the display. However the transmitter may not be about to respond to this request. For instance in a non-real-time video streaming application, the transmitter cannot respond to an INTRA request from a decoder. Therefore the decoder freezes the picture until the next INTRA frame is received. In a real-time application such as video-conferencing, the transmitter may not be able to respond. For instance, in a multi-party confer-

ence, the encoder may not be able to respond to individual requests. Again the decoder freezes the picture until an INTRA frame is output by the transmitter.

SUMMARY OF THE INVENTION

According to a first aspect of the invention there is provided a method of encoding a video signal representing a sequence of pictures, the method employing both non-temporal prediction and temporal prediction, wherein the method comprises, for each picture that forms a reference picture for the temporal prediction of another picture, associating with each such picture an indicator indicating the temporal order of the reference picture in the encoded video signal relative to the other reference pictures in the encoded video signal.

Thus each reference picture (e.g. I-frames and P-frames) is associated with a sequence number. Preferably the indicator is incremented each time a reference picture is encoded. Most advantageously the indicator is incremented by one each time a reference picture is encoded. Thus the indicator is incremented by one from the previous reference picture.

If multi-layer coding is used, preferably this indicator is incremented by one from the previous reference picture in the same enhancement layer.

Including this indicator means that a decoder is capable of determining whether a reference picture has been lost and to take appropriate action, if available. This is the case even if the transport protocol does not include sequence information about the packets being transmitted or the transmitter uses a varying encapsulation strategy. For example, if the transmitter encapsulates a varying number of GOBs in one packet, receivers cannot reliably know how many GOBs or entire pictures were lost even if they could detect packet losses from packet sequence numbers.

The invention also enables a decoder to differentiate B picture losses from reference picture losses. Consequently, decoders can continue decoding after a B picture loss instead of waiting for the next INTRA picture.

In addition a decoder may continue decoding lower enhancement layers if a reference picture from a higher enhancement layer is lost.

The reference picture order number may be in respect of the whole picture or part of a picture. In the former case, typically the reference picture order number is included in a picture header. In a preferred implementation of the invention, the video signal is encoded according to the H.263 standard and the indicator is included in the Supplemental Enhancement Information. Where the RPON is in respect of part of a picture the reference picture order number may be included in the picture segment headers or macroblock headers of the encoded picture.

In accordance with a second aspect of the invention there is provided a method of decoding an encoded video signal representing a sequence of pictures, the method comprising receiving an encoded video signal, decoding each received picture, examining for each picture to be decoded that forms a reference picture for another picture an indicator representing the temporal order of a reference frame and, when the indicator does not follow consecutively from an immediately preceding decoded reference frame, detecting a lost reference frame.

Preferably the decoder sends a request to a transmitter to encode a picture in a non-temporal manner when the indicator does not follow consecutively from an immediately preceding decoded reference frame.

In accordance with a third aspect of the invention there is provided an encoded video signal wherein for each picture

5

that forms a reference picture for the temporal prediction of another picture, an indicator is associated with each such reference picture indicating the temporal order of the reference pictures in the encoded video stream.

In accordance with a fourth aspect of the invention there is provided a video encoder comprising an input for receiving a video signal representing a sequence of pictures and for generating encoded pictures, said encoder being arranged to employ both non-temporal prediction and temporal prediction, wherein the encoder is arranged, for each picture that forms a reference picture for the temporal prediction of another picture, to associate with each reference picture an indicator indicating the temporal order of the reference picture in the encoded video signal relative to other reference pictures in the encoded video signal.

Preferably the indicator is incremented each time a reference picture is encoded.

In accordance with a fifth aspect of the invention there is provided a video decoder comprising an input for receiving an encoded video signal representing a sequence of pictures, a decoder for decoding each received picture, the decoder being arranged to examine for each picture to be decoded that forms a reference picture for another picture an indicator representing the temporal order of a reference frame and, when the indicator does not follow consecutively from an immediately preceding decoded reference frame, to detect a lost reference frame.

The invention also relates to a portable radio communications device including an encoder and/or a decoder as described.

BRIEF DESCRIPTION OF THE DRAWINGS

The invention will now be described, by way of example only, with reference to the accompanying drawings, in which:

FIG. 1 shows a multimedia mobile communications system;

FIG. 2 shows an example of the multimedia components of a multimedia terminal;

FIG. 3 shows an example of a video codec;

FIG. 4 illustrates the operation of a first implementation of a video encoder according to a first embodiment of the invention;

FIG. 5 illustrates the operation of a second implementation of a video encoder according to a first embodiment of the invention;

FIG. 6 shows the syntax of a bit stream as known according to H.263;

FIG. 7 shows a first example of a bit stream output by an encoder according to the invention;

FIG. 8 shows a second example of a bit stream output by an encoder according to the invention;

FIG. 9 shows a third example of a bit stream output by an encoder according to the invention;

FIG. 10 illustrates enhancement layers used in video coding for SNR scalability; and

FIG. 11 illustrates enhancement layers used in video coding for spatial scalability.

DETAILED DESCRIPTION OF THE INVENTION

FIG. 1 shows a typical multimedia mobile communications system. A first multimedia mobile terminal 1 communicates with a second multimedia mobile terminal 2 via a radio link 3 to a mobile communications network 4. Control data is sent between the two terminals 1,2 as well as the multimedia data.

6

FIG. 2 shows the typical multimedia components of a terminal 1. The terminal comprises a video codec 10, an audio codec 20, a data protocol manager 30, a control manager 40, a multiplexer/demultiplexer 50 and a modem 60 (if the required). The video codec 10 receives signals for coding from a video capture device of the terminal (not shown) (e.g. a camera) and receives signals for decoding from a remote terminal 2 for display by the terminal 1 on a display 70. The audio codec 20 receives signals for coding from the microphone (not shown) of the terminal 1 and receive signals for decoding from a remote terminal 2 for reproduction by a speaker (not shown) of the terminal 1.

The control manager 40 controls the operation of the video codec 10, the audio codec 20 and the data protocol manager 30. However, since the invention is concerned with the operation of the video codec 10, no further discussion of the audio codec 20 and protocol manager 30 will be provided.

FIG. 3 shows an example of a video codec 10 according to the invention. The video codec comprises an encoder part 100 and a decoder part 200. The encoder part 100 comprises an input 101 for receiving a video signal from a camera or video source (not shown) of the terminal 1. A switch 102 switches the encoder between an INTRA-mode of coding and an INTER-mode.

In INTRA-mode, the video signal from the input 101 is transformed into DCT co-efficients by a DCT transformer 103. The DCT coefficients are then passed to a quantiser 104 that quantises the coefficients. Both the switch 102 and the quantiser 104 are controlled by an encoding control manager 105 of the video codec, which also receives feedback control from the receiving terminal 2 by means of the control manager 40.

In INTER mode, the switch 102 is operated to accept from a subtractor 106 the difference between the signal from the input 101 and a previous picture which is stored in a picture store 107. The difference data output from the subtractor 106 represents the prediction error between the current picture and the previous picture stored in the picture store 107. The data in the picture store 107 is generated by passing the data output by the quantiser through an inverse quantiser 108 and applying an inverse DCT transform 109 to the inverse-quantised data. The resulting data is added to the contents of the picture store 107 by adder 110. A motion estimator 111 may generate motion compensation data from the data in the picture store 107 in a conventional manner.

The encoding control manager 105 decides whether to apply INTRA or INTER coding or whether to code the frame at all on the basis of either the output of the subtractor 106 or in response to feedback control data received a receiving decoder. When not responding to feedback control data, the encoder typically encodes a frame as an INTRA-frame either only at the start of coding (all other frames being P-frames), or at regular periods e.g. every 5 s, or when the output of the subtractor exceeds a threshold i.e. when the current picture and that stored in the picture store 107 are too dissimilar. The encoder may also be programmed to encode frames in a particular regular sequence e.g. I B B P B B P B B P B B P B I B B P etc. In addition the encoding control manager may decide not to code a received frame at all. This happens when the similarity between the current frame and the reference frame is so high that the encoder decides not to encode the current frame. The encoding control manager operates the switch accordingly.

The video codec outputs the quantised DCT coefficients 112a, the quantising index 112b (i.e. the details of the quantiser used), an INTRA/INTER flag 112c to indicate the mode of coding performed (I or P/B), a transmit flag 112d to indi-

cate the number of the frame being coded and the motion vectors **112e** for the picture being coded. These are multiplexed together by the multiplexer **50** together with other multimedia signals.

The decoder part **200** of the video codec **10** comprises an inverse quantiser **120**, an inverse DCT transformer **121**, a motion compensator **122**, a picture store **123** and a controller **124**. The controller **124** receives video codec control signals demultiplexed from the encoded multimedia stream by the demultiplexer **50**. In practice the controller **105** of the encoder and the controller **124** of the decoder may be the same processor.

The operation of an encoder according to the invention will now be described. The video codec **10** receives a video signal to be encoded. The encoder **100** of the video codec encodes the video signal by performing DCT transformation, quantisation and motion compensation. The decoded video data is then output to the multiplexer **50**. The multiplexer **50** multiplexes the video data from the video codec **10** and control data from the control manager **40** (as well as other signals as appropriate) into a multimedia signal. The terminal **1** outputs this multimedia signal to the receiving terminal **2** via the modem **60** (if required).

In a first embodiment of the invention, each time the encoder encodes a frame which may form the reference frame for a subsequent frame, the encoding control manager **105** associates with the frame a so-called Reference Picture Order Number (RPON). For example, a RPON is associated with every I or P frame of a video signal but not with a B-frame. The RPON value is incremented each time a successive reference picture is encoded, preferably by 1.

The encoding control manager **105** outputs the RPON codeword on output **112f** which indicates the Reference Picture Order Number associated with the encoded frame. This is multiplexed into the video bitstream by a multiplexer.

FIG. **4** illustrates the operation of the encoder. In this embodiment, the encoder is arranged to output an I-frame when the similarity between the frame being coded and the reference frame is less than a first threshold i.e. when the output from the subtractor **106** is greater than a first threshold. Otherwise the encoder outputs P-frames. The first line of FIG. **4** represents the frames of data received from a capture input device and input to the video encoder on input **101**. The second line of FIG. **4** represents those frames of the input signal that the encoder decides to encode and the coding mode used to encode each frame. As mentioned above some, the encoding control manager may decide that a frame is not to be coded; this is exemplified in FIG. **4** by the fact that frames **2**, **3** and **11** are not coded.

Frame **1** is coded in INTRA-mode; frame **4** is encoded as a P-frame with reference to frame **1**; frame **5** is encoded as a P-frame with reference to frame **4**; frame **6** is encoded as a P-frame with reference to frame **5**; frame **7** is encoded as a P-frame with reference to frame **6**; frame **8** is encoded as an I-frame; frame **9** is encoded as a P-frame with reference to frame **8**; frame **10** is encoded as a P-frame with reference to frame **9**; frame **12** is encoded as a P-frame with reference to frame **10**.

In this embodiment all (but the last) of the encoded frames act as the reference frame for a later frame. Thus a RPON is associated with all of the frames to be coded, as shown in the third line of FIG. **4**. As can be seen, the RPON is incremented by 1 each time.

The fourth line of FIG. **4** shows the Temporal Reference (TR) of the encoded frame. This is a field included in H.263 and the value of TR is formed by incrementing its value in the temporally previous reference picture header by one plus the

number of skipped or non-reference pictures since the previously transmitted one. Thus in the example shown in FIG. **4** the TR shown for each frame is the same as the original number in the original signal input to **102**.

FIG. **5** shows a second embodiment of an encoder according to the invention. In this embodiment, the encoder is arranged to code the frames according to the regular sequence I B B P B B P B B P B B P B B P. The first line of FIG. **5** shows the input frames and the second line shows the coded frames and their coding mode, I, P or B.

The frames are received from a video capture device in the order 1, 2, 3, 4, 5, 6 etc. and are displayed in this order i.e. the decoded frames are displayed in the order I1, B2, B3, P4, B5, B6, P7 etc. However the video bit stream is compressed, transmitted and decoded in the following order I1, P4, B2, B3, P7, B5, B6 etc. This is because each B-frame requires preceding and succeeding reference frames before they can be encoded/decoded i.e. frame B2 requires frame I1 and P4 to be encoded/decoded before frame B2 can be encoded/decoded.

As explained previously, B-frames are inserted between anchor picture pairs of I- and/or P-frames and are predicted from either one or both of these anchor pictures. Thus in the illustration given in FIG. **5**, Frame **1** is coded in INTRA-mode; frame **4** is encoded as a B-frame with reference to frame **1** and/or **6**; frame **5** is encoded as a B-frame with reference to frame **1** and/or **6**; frame **6** is encoded as a P-frame with reference to frame **1**; frame **7** is encoded as a B-frame with reference to frame **6** and/or **9**; frame **8** is encoded as an B-frame with reference to frame **6** and/or **9**; frame **9** is encoded as a P-frame with reference to frame **6**; frame **10** is encoded as a B-frame with reference to frame **9** and/or **13** (not shown); frame **12** is encoded as a B-frame with reference to frame **9** and/or **13** and so on.

In this embodiment each I-frame and P-frame of the encoded sequence acts as a reference frame for another frame. However a B-frame does not act as a reference picture for any other frame. Thus a RPON is associated with all of the I-frames and P-frames, as shown in the third line of FIG. **5**. As can be seen, the RPON is incremented by 1 each time. Thus frame **1** (an I-frame) has a RPON of 1, frame **4** (a P-frame) has a RPON of 2 and frame **9** (a P-frame) has a RPON of 3.

The fourth line of FIG. **5** shows the Temporal Reference (TR) of the encoded frame. As in the example shown in FIG. **4**, the TR shown for each frame is the same as the order of occurrence in the original signal input to **10**.

Considering the terminal **1** as receiving coded video data from terminal **2**, the operation of the video codec **10** will now be described with reference to its decoding role. The terminal **1** receives a multimedia signal from the transmitting terminal **2**. The demultiplexer **50** demultiplexes the multimedia signal and passes the video data to the video codec **10** and the control data to the control manager **40**. The decoder **200** of the video codec decodes the encoded video data by inverse quantising, inverse DCT transforming and motion compensating the data. The controller **124** of the decoder checks the integrity of the received data and, if an error is detected, attempts to conceal the error in a manner to be described below. The decoded, corrected and concealed video data is then output for reproduction on a display **70** of the receiving terminal **1**.

Errors in video data may occur at the picture level, the GOB level or the macroblock level. Error checking may be carried out at any or all of these levels.

Considering first the signal as shown in FIG. **4**, when a decoder according to the invention receives this signal each frame of the signal is decoded in a conventional manner and then displayed on a display means. The decoded frame may be error corrected and error concealed in a conventional man-

ner. Each time a frame is decoded, the decoder examines the TR field to determine when the frame is to be displayed. If the TRs are not consecutive (e.g. the decoder receives a frame with TR=1 and then a frame with TR=4) the decoder holds the frame **1** on the display for 3 times the usual frame period, as is conventional. The decoder also examines the RPON of the received frames. In the case shown in FIG. **4** the decoder receives frame **1** and sees that this frame has a RPON=1; the decoder then receives a frame with TR=4 and RPON=2. The decoder compares the RPON of the currently received frame with the RPON of the previously received frame and calculates the difference between the RPON values. In this case the difference is 1 and the decoder therefore knows that no reference pictures have been lost between the current frame and the previous decoded reference frame. The decoder therefore continues to decode the signal in a conventional manner.

Let us now assume that the decoder is unable to reconstruct frame **5** (this could be due to the data being greatly corrupted or being lost altogether) and the next frame received and decoded by the decoder is frame **6**. The decoder compares the RPON of the currently received frame (frame **6**) with the RPON of the previously received and decoded reference frame (frame **4**) and calculates the difference between the RPON values. In this case the difference is 2 and the decoder therefore knows that a reference picture has been lost between transmission of the current frame and that of the previous frame. If the decoder has the facility to send control feedback data to the transmitting video encoder the decoder can send a request to the transmitting video encoder to encode a frame as an INTRA-frame and so stop the temporal error propagation that would result from frame **6** being decoded with reference to frame **4**.

Considering now the signal as shown in FIG. **5**, when a decoder according to the invention receives this signal each frame of the signal is decoded in a conventional manner and then displayed on a display means. The decoded frame may be error corrected and error concealed in a conventional manner. Each time a frame is decoded, the decoder examines the TR field to determine when the frame is to be displayed. The decoder also examines the RPON of the received frames.

In the case shown in FIG. **5** the decoder receives frame **1** and sees that this frame has a RPON=1. The decoder decodes this frame in a conventional INTRA-mode manner. The next frame received by the decoder is then frame **6**, with TR=6 and RPON=2. The decoder compares the RPON of the currently received frame (frame **6**) with the RPON of the previously received and decoded reference frame (frame **1**) and calculates the difference between the RPON. In this case the difference is 1 and the decoder therefore knows that no reference pictures have been lost between transmission of the current frame and that of the previous decoded reference frame. The decoder then decodes frame **6** with reference to frame **1**.

The decoder then receives a frame with TR=4 and no RPON. In this case the decoder makes no further use of the RPON and decodes frame **4** with reference to decoded frames **1** and **6**.

Let us now assume that the decoder is unable to reconstruct frame **5** (this could be due to the data being greatly corrupted or being lost altogether). The fact that B-frame **5** has been lost is of no consequence to the decoder as the B-frame does not form a reference picture for any other frame and thus its loss will not introduce any temporal error propagation.

The next frame to be received is frame **9**. However, let us now assume that the decoder is unable to reconstruct frame **9**, which is a P-frame (this could be due to the data being greatly corrupted or being lost altogether). The decoder may therefore be unable to decode successfully any of frames **7**, **8**, **10** or

12 since these may all be predicted, in part at least, with reference to frame **9**. Typically, in this situation, the decoder will freeze the displayed picture.

The next frame received and decoded by the decoder is frame **13**. The decoder compares the RPON of the currently received reference frame (frame **13**) with the RPON of the previously received and decoded reference frame (frame **6**) and calculates the difference between the RPON. In this case the difference is 2 and the decoder therefore knows that a reference picture has been lost between the current frame and the previous decoded reference frame. If the decoder has the facility to send control feedback data to the transmitting video encoder the decoder can send a request to the transmitting video encoder to encode a frame as an INTRA-frame and so stop the temporal error propagation that would result from frame **13** being decoded with reference to frame **6**.

How the reference picture order number may be included in the encoded signal will now be addressed with reference to the H.263 video coding standard.

FIG. **6** shows the syntax of a bit stream as known according to H.263. The following implementations describe the GOB format but it will be clear to a skilled person that the invention may also be implemented in the slice format.

As mentioned already, the bit stream has four layers: the picture layer, picture segment layer, macroblock layer and block layer. The picture layer comprises a picture header followed by data for the Group of Blocks, eventually followed by any optional end-of-sequence code and stuffing bits.

The prior art H.263 bit stream is formatted as shown in FIG. **6**. A descriptor for each part is given below:

PSC The picture start code (PSC) indicates the start of the picture
 TR The Temporal Reference (TR) is formed by incrementing its value in the temporally previous reference picture header by one plus the number of skipped or non-referenced pictures since the previously transmitted one
 PTYPE Amongst other things, PTYPE includes details of the picture coding type i.e. INTRA or INTER
 PQQUANT A codeword that indicates the quantiser to be used for the picture until updated by any subsequent quantiser information
 CPM A codeword that signals the use of optional continuous presence multipoint and video multiplex (CPM) mode
 PSBI Picture Sub-Bit stream Indicator—only present if CPM is set
 TR_B Present if the frame is a bi-directionally predicted frame (known as a PB-frame)
 DBQUANT Present if a bidirectional frame
 PEI This relates to extra insertion information and is set to “1” to indicate the presence of the following optional data fields PSUPP and PEI. PSUPP and PEI are together known as Supplemental Enhancement Information, which is further defined in Annex L of H263.
 GOBS Is the data for the group of blocks for the current picture
 ESTF A stuffing codeword provided to attain byte alignment before EOS
 EOS A codeword indicating the end of the data sequence for the picture
 PSTUF A stuffing codeword to allow for byte alignment of the next picture start code PSC

The structure as shown in FIG. **4** does not include the optional PLUSTYPE data field. PSBI is only present if indicated by CPM. TRB and DBQUANT are only present if PTYPE indicates use of a so-called PB frame mode (unless

the PLUSTYPE field is present and the use of DBQUANT is indicated therein). These issues are addressed in more detail in the H.263 specification.

The following paragraphs outline possible implementations of the bit-stream output by an encoder according to the first aspect of the invention.

The reference picture order number may be incorporated into a H.263 bit stream as follows. FIG. 7 shows an example of a bit stream output by an encoder according to the first implementation of the invention. As shown in FIG. 7, the bit stream includes a further codeword RPON which is a codeword indicating the reference picture order number. This is inserted by an encoder according to the invention, as described above.

Alternatively, the reference picture order number may be included in the Supplemental Enhancement Information PSUPP (see Annex L of H.263 and FIG. 4). The supplemental information may be present in the bit stream even though the decoder may not be capable of providing the enhanced capability to use it, or even to properly interpret it. Simply discarding the supplemental information is allowable by decoders unless a requirement to provide the requested capability has been negotiated by the transmitter and receiver.

If PEI is set to "1", then 9 bits follow consisting of 8 bits of data (PSUPP) and then another PEI bit to indicate if a further 9 bits follow and so on.

The PSUPP data consists of a 4-bit function type indication FTYPE, followed by a 4-bit parameter data size specification DSIZE followed by DSIZE octets of function parameter data, optionally followed by another FTYPE and so on. It is known to use this PSUPP codeword to signal various situations such as: to indicate a full-picture or partial-picture freeze or freeze-release request with or without resizing; to tag particular pictures or sequences of pictures within the video stream for external use; or to convey chroma key information for video compositing.

To implement the invention using the Supplemental Enhancement Information, a further FTYPE is defined as Reference Picture Order Number.

FIG. 8 illustrates the example where a parameter RPON is included in the SEI of the picture header. The FTYPE is defined as RPON. The DSIZE specifies the size of the parameter and the following octet is the parameter data i.e. the value of RPON. From this value a receiving decoder can determine whether a reference picture has been lost.

Alternatively, the information may be contained in the additional Supplemental Enhancement Information as specified in a "Draft of new Annex W: Additional Supplementary Enhancement Information Specification" P. Ning and S. Wenger, ITU-T Study Group 16 Question 15 Document Q15-I-58, November 1999.

In this draft proposal, FTYPE 14 is defined as "Picture Message". When this FTYPE is set, the picture message function indicates the presence of one or more octets representing message data. The first octet of the message data is a message header with the structure shown in FIG. 9 i.e. CONT, EBIT and MTYPE. DSIZE is equal to the number of octets in the message data corresponding to a picture message function, including the first octet message header.

The continuation field CONT, if equal to 1, indicates that the message data associated with the picture message is part of the same logical message as the message data associated with the next picture message function. The End Bit Position field EBIT specifies the number of least significant bits that shall be ignored in the last message octet. Further details of these fields can be found in the draft of Annex W referred to above.

The field MTYPE indicates the type of message. Various types of message are suggested in the draft of Annex W. According to the invention one type e.g. MTYPE 12 is defined as RPON or Picture Number. The message contains two data bytes that carry a 10-bit Picture Number. Consequently, DSIZE shall be 3, CONT shall be 0, and EBIT shall be 6. Picture Number shall be incremented by 1 for each coded and transmitted I or P picture or PB or Improved PB frame, in a 10-bit modulo operation. For EI and EP pictures, Picture Number shall be incremented for each EI or EP picture within the same scalability enhancement layer. For B pictures, Picture Number shall be incremented relative to the value in the most recent non-B picture in the reference layer of the B picture which precedes the B picture in bitstream order (a picture which is temporally subsequent to the B picture). If adjacent pictures in the same enhancement layer have the same temporal reference, and if the reference picture selection mode (see Annex N) is in use, the decoder shall regard this occurrence as an indication that redundant copies have been sent of approximately the same pictured scene content, and all of these pictures shall share the same Picture Number. If the difference (modulo 1024) of the Picture Numbers of two consecutively received non-B pictures in the same enhancement layer is not 1, and if the pictures do not represent approximately the same pictured scene content as described above, a loss of pictures or corruption of data may be inferred by the decoder. The value of RPON is defined in the octet following the message header.

In a specific example, this message contains one data byte, i.e., DSIZE is 2, CONT is 0, and EBIT is 0.

The Reference Picture Order Number is incremented by one from the corresponding number of the previous coded reference picture. The least significant 8-bits of the result of the incrementation is placed in the data byte associated with this message.

The invention may also be implemented in accordance with Annex U of H.263.

The above description has made reference to encoded video streams in which bi-directionally predicted pictures (B-pictures) are encoded. As mentioned earlier, B-pictures are never used as reference pictures. Since they can be discarded without impacting the picture quality of future pictures, they provide temporal scalability. Scalability allows for the decoding of a compressed video sequence at more than one quality level. In other words, a scalable multimedia clip can be compressed so that it can be streamed over channels with different data rates and still be decoded and played back in real-time.

Thus the video stream may be decoded in different ways by differing decoders. For instance, a decoder can decide only to decode the I- and P-pictures of a signal, if this is the maximum rate of decoding that the decoder can attain. However if a decoder has the capacity, it can also decode the B-pictures and hence increase the picture display rate. Thus the perceived picture quality of the displayed picture will be enhanced over a decoder that only decodes the I- and P-pictures.

Scalable multimedia is typically ordered so that there are hierarchical layers of data. A base layer contains a basic representation of the multimedia clip whereas enhancement layers contain refinement data on top of underlying layers. Consequently, the enhancement layers improve the quality of the clip.

Scalability is a desirable property for heterogeneous and error prone environments. This property is desirable in order to counter limitations such as constraints on bit rate, display resolution, network throughput, and decoder complexity.

Scalability can be used to improve error resilience in a transport system where layered coding is combined with transport prioritisation. The term transport prioritisation here refers to various mechanisms to provide different qualities of service in transport, including unequal error protection, to provide different channels having different error/loss rates. Depending on their nature, data are assigned differently. For example, the base layer may be delivered through a channel with a high degree of error protection, and the enhancement layers may be transmitted through more error-prone channels.

Generally, scalable multimedia coding suffers from a worse compression efficiency than non-scalable coding. In other words, a multimedia clip encoded as a scalable multimedia clip with enhancement layers requires greater bandwidth than if it had been coded as a non-scalable single-layer clip with equal quality. However, exceptions to this general rule exist, for example the temporally scalable B-frames in video compression.

The invention may be applied to other scalable video compression systems. For instance, in H.263 Annex O, two other forms of scalability are defined: signal-to-noise (SNR) scalability and spatial scalability. Spatial scalability and SNR scalability are closely related, the only difference being the increased spatial resolution provided by spatial scalability. An example of SNR scalable pictures is shown in FIG. 10. SNR scalability implies the creation of multi-rate bit streams. It allows for the recovery of coding errors, or differences between an original picture and its reconstruction. This is achieved by using a finer quantiser to encode the difference picture in an enhancement layer. This additional information increases the SNR of the overall reproduced picture.

Spatial scalability allows for the creation of multi-resolution bit streams to meet varying display requirements and/or constraints. A spatially scalable structure is illustrated in FIG. 11. It is essentially the same as in SNR scalability except that a spatial enhancement layer attempts to recover the coding loss between an up-sampled version of the reconstructed reference layer picture and a higher resolution version of the original picture. For example, if the reference layer has a quarter common intermediate format (QCIF) resolution, and the enhancement layer has a common intermediate format (CIF) resolution, the reference layer picture must be scaled accordingly such that the enhancement layer picture can be predicted from it. The QCIF standard allows the resolution to be increased by a factor of two in the vertical direction only, horizontal direction only, or both the vertical and horizontal directions for a single enhancement layer. There can be multiple enhancement layers, each increasing the picture resolution over that of the previous layer. The interpolation filters used to up-sample the reference layer picture are explicitly defined in the H.263 standard. Aside from the up-sampling process from the reference to the enhancement layer, the processing and syntax of a spatially scaled picture are identical to those of an SNR scaled picture.

In either SNR or spatial scalability, the enhancement layer pictures are referred to as EI- or EP-pictures. If the enhancement layer picture is upwardly predicted from a picture in the reference layer, then the enhancement layer picture is referred to as an Enhancement-I (EI) picture. In this type of scalability, the reference layer means the layer "below" the current enhancement layer. In some cases, when reference layer pictures are poorly predicted, over-coding of static parts of the picture can occur in the enhancement layer, causing an unnecessarily excessive bit rate. To avoid this problem, forward prediction is permitted in the enhancement layer. A picture that can be predicted in the forward direction from a previous

enhancement layer picture or, alternatively, upwardly predicted from the reference layer picture is referred to as an Enhancement-P (EP) picture. Note that computing the average of the upwardly and forwardly predicted pictures can provide bi-directional prediction for EP-pictures. For both EI- and EP-pictures, upward prediction from the reference layer picture implies that no motion vectors are required. In the case of forward prediction for EP-pictures, motion vectors are required.

According to the invention, if the encoder is capable of multi-layer coding (for example as discussed in Annex O of H.263) the reference pictures of each layer are given consecutive Reference Picture Order Numbers. These may be associated with the enhancement layer number (ELNUM) of the current picture. The Reference Picture Order Number is incremented by one from the corresponding number of the previous coded reference picture in the same enhancement layer.

As shown in FIGS. 10 and 11, the pictures of the enhancement layer may be predicted from a preceding picture of the enhancement layer and/or from the equivalent I- or P-picture of the base layer. The enhancement layer may not be predicted from a B-picture in the reference layer.

If adjacent pictures in the same enhancement layer have the same temporal reference, and if Annex N or Annex U of H.263 is in use, the decoder preferably regards this occurrence as an indication that redundant copies have been sent of approximately the same pictured scene content, and all of these pictures then share the same RPON.

A decoder according to the invention, on receipt of a multi-layer signal as described above, attempts to decode the signal in a conventional manner. In each layer, each time a reference picture is decoded, the decoder examines the RPON of the decoded picture. If the decoder determines that a reference picture has been lost from an enhancement layer, the decoder ceases to display pictures from the enhancement layer until an EI-picture is received. The decoder continues to decode the base layer as described earlier.

The invention is not intended to be limited to the video coding protocols discussed above: these are intended to be merely exemplary. The invention is applicable to any video coding protocol in which temporal prediction may be used. The addition of the information as discussed above allows a receiving decoder to determine that a reference picture has been lost and to take appropriate action.

What is claimed is:

1. A method of encoding a video signal using an encoder to form an encoded video signal, the video signal representing a sequence of pictures, the method comprising the encoder using an independent numbering scheme, to assign consecutive reference pictures in encoding order with respective sequence indicator values that differ with respect to each other by a predetermined amount independent of one or more of the number of non-reference pictures encoded between consecutive reference pictures and the number of non-coded pictures between consecutive reference pictures.

2. A method according to claim 1, comprising the encoder incrementing the sequence indicator value by one between consecutively encoded reference pictures.

3. A method according to claim 1, comprising the encoder providing the sequence indicator value for a particular picture in a corresponding picture header.

4. A method according to claim 1, comprising the encoder encoding the video signal according to the H.263 video coding standard and providing the sequence indicator value for a particular picture in the corresponding Supplemental Enhancement Information of the H.263 bit-stream.

15

5. A method according to claim 1, comprising the encoder associating a sequence indicator value with the whole of a picture.

6. A method according to claim 1, comprising the encoder associating a sequence indicator value with part of a picture.

7. A method according to claim 6, comprising the encoder providing the sequence indicator value in a picture segment header or a macroblock header of an encoded picture.

8. A method according to claim 1, comprising the encoder encoding the video signal using multi-layer coding to produce an encoded video signal with multiple layers and providing respective sequence indicator values for each of said multiple layers of the multi-layer coded video signal.

9. A method according to claim 1, comprising the encoder using a fixed value as the predetermined amount.

10. A method according to claim 1, comprising the encoder using sequence indicator values which are reference picture order numbers.

11. A method according to claim 1, comprising the encoder encoding reference pictures in I-picture format or P-picture format.

12. A method according to claim 1, comprising the encoder encoding non-reference pictures in B-picture format.

13. A method according to claim 1, comprising the encoder incrementing the sequence indicator value by said predetermined amount between consecutively encoded reference pictures when there are no non-reference pictures.

14. A non-transitory computer readable storage medium comprising a computer program embodied thereon, the computer program comprising computer program code for performing the encoding method of claim 1.

15. A method of decoding an encoded video signal using a decoder to form a decoded video signal, the video signal representing a sequence of pictures, the method comprising:

the decoder examining decoded reference pictures to identify a difference in respective sequence indicator values assigned to consecutively encoded reference pictures; the decoder comparing the identified difference in said sequence indicator values on the basis of an independent numbering scheme in which consecutive reference pictures in encoding order are assigned sequence indicator values that differ with respect to each other by a predetermined amount, independent of one or more of the number of non-reference pictures encoded between consecutive reference pictures, and the number of non-coded pictures between consecutive reference pictures; and

the decoder detecting corruption or loss of a reference picture if said identified difference in sequence indicator values is more than said predetermined amount.

16. A method according to claim 15, comprising the decoder comparing the sequence indicator value assigned to a particular received and decoded reference picture with the sequence indicator value assigned to an immediately preceding received and decoded reference picture.

17. A method according to claim 15, further comprising the decoder sending a request for an encoder to provide a picture encoded in a non-temporally-predicted manner when said identified difference differs from said predetermined amount.

18. A method according to claim 15, comprising the decoder using a predetermined amount of one in said comparison when the sequence indicator values assigned to consecutive reference pictures in encoding order differ by one.

19. A method according to claim 15, comprising the decoder obtaining the sequence indicator value for a particular picture from a corresponding picture header.

16

20. A method according to claim 15, comprising the decoder receiving a video signal encoded according to the H.263 video coding standard and obtaining the sequence indicator value for a particular picture from the corresponding Supplemental Enhancement Information of the H.263 bit-stream.

21. A method according to claim 15, wherein a sequence indicator value is associated with the whole of a picture.

22. A method according to claim 15, wherein a sequence indicator value is associated with part of a picture.

23. A method according to claim 22, comprising the decoder obtaining the sequence indicator value from a picture segment header or a macroblock header of an encoded picture.

24. A method according to claim 15, comprising the decoder examining identified differences in sequence indicator values provided for each layer of an encoded video signal that comprises multiple layers in order to detect corruption or loss of reference pictures within said layers.

25. A method according to claim 15, wherein the predetermined amount is a fixed value.

26. A method according to claim 15, wherein the sequence indicator value is a reference picture order number.

27. A method according to claim 15, wherein reference pictures are encoded in I-picture format or P-picture format.

28. A method according to claim 15, wherein non-reference pictures are encoded in B-picture format.

29. A method according to claim 15, wherein the sequence indicator value is incremented by said predetermined amount between consecutively encoded reference pictures when there are no non-reference pictures.

30. A non-transitory computer readable storage medium comprising a computer program embodied thereon, the computer program comprising computer program code for performing the decoding method of claim 15.

31. An apparatus for encoding a video signal representing a sequence of pictures to form an encoded video signal, wherein the apparatus is configured to use an independent numbering scheme to assign consecutive reference pictures in encoding order with respective sequence indicator values that differ with respect to each other by a predetermined amount independent of one or more of the number of non-reference pictures encoded between consecutive reference pictures, and the number of non-coded pictures between consecutive reference pictures.

32. An apparatus according to claim 31, wherein the apparatus is configured to increment the sequence indicator value by one between consecutively encoded reference pictures.

33. An apparatus according to claim 31, wherein the apparatus is configured to provide the sequence indicator value for a particular picture in a corresponding picture header.

34. An apparatus according to claim 31, wherein the apparatus is configured to encode the video signal according to the H.263 video coding standard and to provide the sequence indicator value for a particular picture in the corresponding Supplemental Enhancement Information of the H.263 bit-stream.

35. An apparatus according to claim 31, wherein the apparatus is configured to associate a sequence indicator value with the whole of a picture.

36. An apparatus according to claim 31, wherein the apparatus is configured to associate a sequence indicator value with part of a picture.

37. An apparatus according to claim 36, wherein the apparatus is configured to provide the sequence indicator value in a picture segment header or a macroblock header of an encoded picture.

17

38. An apparatus according to claim 31, wherein the apparatus is configured to encode the video signal using multi-layer coding to produce an encoded video signal with multiple layers and to provide respective sequence indicator values for each of said multiple layers of the multi-layer coded video signal.

39. A portable radio communications device comprising an apparatus for encoding a video signal according to claim 31.

40. A multimedia terminal device comprising an apparatus for encoding a video signal according to claim 31.

41. An apparatus according to claim 31, wherein the apparatus is configured to use a fixed value as the predetermined amount.

42. An apparatus according to claim 31, wherein the apparatus is configured to use sequence indicator values which are reference picture order numbers.

43. An apparatus according to claim 31, wherein the apparatus is configured to encode reference pictures in I-picture format or P-picture format.

44. An apparatus according to claim 31, wherein the apparatus is configured to encode non-reference pictures in B-picture format.

45. An apparatus according to claim 31, wherein the apparatus is configured to increment the sequence indicator value by said predetermined amount between consecutively encoded reference pictures when there are no non-reference pictures.

46. An apparatus for decoding an encoded video signal representing a sequence of pictures to form a decoded video signal, wherein the apparatus is configured to:

examine decoded reference pictures to identify a difference in respective sequence indicator values assigned to consecutively encoded reference pictures;

compare the identified difference in sequence indicator values on the basis of an independent numbering scheme in which consecutive reference pictures in encoding order are assigned sequence indicator values that differ with respect to each other by a predetermined amount, independent of one or more of the number of non-reference pictures encoded between consecutive reference pictures, and the number of non-coded pictures between consecutive reference pictures; and

detect corruption or loss of a reference picture if said identified difference in sequence indicator values is more than said predetermined amount.

47. An apparatus according to claim 46, wherein the apparatus is configured to compare the sequence indicator value assigned to a particular received and decoded reference picture with the sequence indicator value assigned to an immediately preceding received and decoded reference picture.

48. An apparatus according to claim 46, wherein the apparatus is further configured to send a request for an encoder to

18

provide a picture encoded in a non-temporally-predicted manner when said identified difference differs from said predetermined amount.

49. An apparatus according to claim 46, wherein the apparatus is configured to use a predetermined amount of one in said comparison when the sequence indicator values assigned to consecutive reference pictures in encoding order differ by one.

50. An apparatus according to claim 46, wherein the apparatus is configured to obtain the sequence indicator value for a particular picture from a corresponding picture header.

51. An apparatus according to claim 46, wherein the apparatus is configured to receive a video signal encoded according to the H.263 video coding standard and to obtain a sequence indicator value for a particular picture from the corresponding Supplemental Enhancement Information of the H.263 bit-stream.

52. An apparatus according to claim 46, wherein a sequence indicator value is associated with the whole of a picture.

53. An apparatus according to claim 46, wherein a sequence indicator value is associated with part of a picture.

54. An apparatus according to claim 53, wherein the apparatus is configured to obtain the sequence indicator value from a picture segment header or a macroblock header of an encoded picture.

55. An apparatus according to claim 46, wherein the apparatus is configured to examine identified differences in sequence indicator values provided for each layer of an encoded video signal that comprises multiple layers in order to detect corruption or loss of reference pictures within said layers.

56. A portable radio communications device comprising an apparatus for decoding an encoded video signal according to claim 46.

57. A multimedia terminal device comprising an apparatus for decoding an encoded video signal according to claim 46.

58. An apparatus according to claim 46, wherein the predetermined amount is a fixed value.

59. An apparatus according to claim 46, wherein the sequence indicator value is a reference picture order number.

60. An apparatus according to claim 46, wherein the apparatus is configured to decode reference pictures encoded in I-picture format or P-picture format.

61. An apparatus according to claim 46, wherein the apparatus is configured to decode non-reference pictures encoded in B-picture format.

62. An apparatus according to claim 46, wherein the sequence indicator value is incremented by said predetermined amount between consecutively encoded reference pictures when there are no non-reference pictures.

(57) **ABSTRACT**

US 2007/0291849 A1 Dec. 20, 2007

Related U.S. Application Data

- A method and device for coding of digital video sequence, wherein an indication of quantization parameter (QP) is provided in the encoded bit-stream for decoding purposes. The QP related information is indicated by introducing a sequence level quantization parameter value SQP. More specifically, instead of coding the absolute values of picture/slice QPs, an indication of the difference ΔQP between the sequence level quantization parameter SQP and the picture/slice QP is provided. This eliminates the need to transmit a full QP for every picture/slice, and enables a statistically smaller difference value to be transmitted, thus providing a reduction in transmission bit-rate. The difference value is subsequently used in a corresponding decoder to reconstruct the picture/slice QP.

METHOD AND DEVICE FOR INDICATING QUANTIZER PARAMETERS IN A VIDEO CODING SYSTEM

This application is a divisional application of and claims priority to a U.S. patent application Ser. No. 10/421,629, filed Apr. 23, 2003, now U.S. Pat. No. 7,263,125 which is based on and claims priority to U.S. provisional application No. 60/374,667, filed Apr. 23, 2002.

FIELD OF THE INVENTION

The invention relates to a method, an encoder, a decoder and a device for the coding of digital video. More specifically, the invention relates to the indication of quantization parameter (QP) values in a video coding system.

BACKGROUND OF THE INVENTION

Digital video sequences, like ordinary motion pictures recorded on film, comprise a sequence of still images, the illusion of motion being created by displaying the images one after the other, typically at a rate between 15 and 30 frames per second.

Each frame of an uncompressed digital video sequence comprises an array of image pixels. In a commonly used digital video format, known as the Quarter Common Interchange Format (QCIF), a frame comprises an array of 176×144 pixels (i.e. 25,344 pixels). In turn, each pixel is represented by a certain number of bits, which carry information about the luminance and/or colour content of the region of the image corresponding to the pixel. Commonly, a so-called YUV colour model is used to represent the luminance and chrominance content of the image. The luminance, or Y, component represents the intensity (brightness) of the image, while the colour content of the image is represented by two chrominance or colour difference components, labelled U and V.

Colour models based on a luminance/chrominance representation of image content provide certain advantages compared with colour models that are based on a representation involving primary colours (that is Red, Green and Blue, RGB). The human visual system is more sensitive to intensity variations than it is to colour variations and YUV colour models exploit this property by using a lower spatial resolution for the chrominance components (U, V) than for the luminance component (Y). In this way, the amount of information needed to code the colour information in an image can be reduced with an acceptable reduction in image quality.

The lower spatial resolution of the chrominance components is usually attained by sub-sampling. Typically, each frame of a video sequence is divided into so-called "macroblocks", which comprise luminance (Y) information and associated chrominance (U, V) information, which is spatially sub-sampled. FIG. 1 illustrates one way in which macroblocks can be formed. As shown in FIG. 1, a frame of a video sequence represented using a YUV color model, each component having the same spatial resolution. Macroblocks are formed by representing a region of 16×16 image pixels in the original image as four blocks of luminance information, each luminance block comprising an 8×8 array of luminance (Y) values and two, spatially corresponding, chrominance components (U and V) which are sub-sampled by a factor of two in both the horizontal and vertical directions to yield corresponding arrays of 8×8 chrominance (U, V) values. According to certain video coding recommendations, such as International Telecommunications Union (ITU-T)

recommendation H.26L, the block size used within the macroblocks can be other than 8×8 , for example 4×8 or 4×4 (see T. Wiegand, "Joint Model Number 1", Doc. JVT-A003, Joint Video Team (JVT) of ISO/IEC MPEG and ITU-T VCEG, January 2002, Sections 2.2 and 2.3). ITU-T recommendation H.26L also allows macroblocks to be organized together to form so-called "slices". More specifically, each slice is formed from a number of consecutive macroblocks in coding order and is encoded in such a way that it can be decoded independently without making reference to any other slice of the same frame. This arrangement is advantageous, as it tends to limit the propagation of artefacts in the decoded video that may arise due to transmission errors. While there is no specific limitation on the way in which slices may be constructed, one straightforward scheme is to group all the macroblocks in a single row of a frame together as a slice. This arrangement, together with the division of a QCIF format image into 16×16 macroblocks is illustrated in FIG. 2.

As can be seen from FIG. 2, a QCIF image comprises 11×9 macroblocks (in this case grouped into 9 slices of 11 consecutive macroblocks each). If the luminance blocks and chrominance blocks are represented with 8 bit resolution (that is by numbers in the range 0 to 255), the total number of bits required per macroblock is $(16 \times 16 \times 8) + 2 \times (8 \times 8 \times 8) = 3072$ bits. The number of bits needed to represent a video frame in QCIF format is thus $99 \times 3072 = 304,128$ bits. This means that the amount of data required to transmit/record/display an uncompressed video sequence in QCIF format, represented using a YUV colour model, at a rate of 30 frames per second, is more than 9 Mbps (million bits per second). This is an extremely high data rate and is impractical for use in video recording, transmission and display applications because of the very large storage capacity, transmission channel capacity and hardware performance required.

If video data is to be transmitted in real-time over a fixed line network such as an ISDN (Integrated Services Digital Network) or a conventional PSTN (Public Switched Telephone Network), the available data transmission bandwidth is typically of the order of 64 kbits/s. In mobile videotelephony, where transmission takes place at least in part over a radio communications link, the available bandwidth can be as low as 20 kbits/s. This means that a significant reduction in the amount of information used to represent video data must be achieved in order to enable transmission of digital video sequences over low bandwidth communication networks. For this reason, video compression techniques have been developed which reduce the amount of information transmitted while retaining an acceptable image quality.

Video compression methods are based on reducing the redundant and perceptually irrelevant parts of video sequences. The redundancy in video sequences can be categorised into spatial, temporal and spectral redundancy. "Spatial redundancy" is the term used to describe the correlation (similarity) between neighbouring pixels within a frame. The term "temporal redundancy" expresses the fact that objects appearing in one frame of a sequence are likely to appear in subsequent frames, while "spectral redundancy" refers to the correlation between different colour components of the same image.

There is often a significant amount of spatial redundancy between the pixels that make up each frame of a digital video sequence. In other words, the value of any pixel within a frame of the sequence is substantially the same as the value of other pixels in its immediate vicinity. Typically, video coding systems reduce spatial redundancy using a technique known as "block-based transform coding", in which a mathematical transformation, such as a two-dimensional Discrete Cosine

Transform (DCT), is applied to blocks of image pixels. This transforms the image data from a representation comprising pixel values to a form comprising a set of coefficient values representative of spatial frequency components. This alternative representation of the image data reduces spatial redundancy significantly and thereby produces a more compact representation of the image data.

Frames of a video sequence which are compressed using block-based transform coding, without reference to any other frame within the sequence, are referred to as INTRA-coded or I-frames.

Generally, video coding systems not only reduce the spatial redundancy within individual frames of a video sequence, but also make use of a technique known as "motion-compensated prediction", to reduce the temporal redundancy in the sequence. Using motion-compensated prediction, the image content of some (often many) of the frames in a digital video sequence is "predicted" from one or more other frames in the sequence, known as "reference" frames. Prediction of image content is achieved by tracking the motion of objects or regions of an image between a frame to be coded (compressed) and the reference frame(s) using "motion vectors". As in the case of INTRA-coding, motion compensated prediction of a video frame is typically performed macroblock-by-macroblock.

Frames of a video sequence, compressed using motion-compensated prediction, are generally referred to as INTER-coded or P-frames. Motion-compensated prediction alone rarely provides a sufficiently precise representation of the image content of a video frame and therefore it is typically necessary to provide a so-called "prediction error" (PE) frame with each INTER-coded frame. The prediction error frame represents the difference between a decoded version of the INTER-coded frame and the image content of the frame to be coded. More specifically, the prediction error frame comprises values that represent the difference between pixel values in the frame to be coded and corresponding reconstructed pixel values formed on the basis of a predicted version of the frame in question. Consequently, the prediction error frame has characteristics similar to a still image and block-based transform coding can be applied in order to reduce its spatial redundancy and hence the amount of data (number of bits) required to represent it.

In order to illustrate the operation of a video coding system in greater detail, reference will now be made to FIGS. 3 and 4. FIG. 3 is a schematic diagram of a generic video encoder that employs a combination of INTRA- and INTER-coding to produce a compressed (encoded) video bit-stream. A corresponding decoder is illustrated in FIG. 4 and will be described later in the text.

The video encoder **100** comprises an input **101** for receiving a digital video signal from a camera or other video source (not shown). It also comprises a transformation unit **104** which is arranged to perform a block-based discrete cosine transform (DCT), a quantizer **106**, an inverse quantizer **108**, an inverse transformation unit **110**, arranged to perform an inverse block-based discrete cosine transform (IDCT), combiners **112** and **116**, and a frame store **120**. The encoder further comprises a motion estimator **130**, a motion field coder **140** and a motion compensated predictor **150**. Switches **102** and **114** are operated co-operatively by control manager **160** to switch the encoder between an INTRA-mode of video encoding and an INTER-mode of video encoding. The encoder **100** also comprises a video multiplex coder **170** which forms a single bit-stream from the various types of information produced by the encoder **100** for further trans-

mission to a remote receiving terminal or, for example, for storage on a mass storage medium, such as a computer hard drive (not shown).

Encoder **100** operates as follows. Each frame of uncompressed video provided from the video source to input **101** is received and processed macroblock by macroblock, preferably in raster-scan order. When the encoding of a new video sequence starts, the first frame to be encoded is encoded as an INTRA-coded frame. Subsequently, the encoder is programmed to code each frame in INTER-coded format, unless one of the following conditions is met: 1) it is judged that the current macroblock of the frame being coded is so dissimilar from the pixel values in the reference frame used in its prediction that excessive prediction error information is produced, in which case the current macroblock is coded in INTRA-coded format; 2) a predefined INTRA frame repetition interval has expired; or 3) feedback is received from a receiving terminal indicating a request for a frame to be provided in INTRA-coded format.

Operation of the encoder **100** in INTRA-coding mode will now be described. In INTRA-coding mode, the control manager **160** operates the switch **102** to accept video input from input line **118**. The video signal input is received macroblock by macroblock and the blocks of luminance and chrominance values which make up each macroblock are passed to the DCT transformation block **104**. Here a 2-dimensional discrete cosine transform is performed and a 2-dimensional array of DCT coefficients is formed for each block.

The DCT coefficients for each block are passed to the quantizer **106**, where they are quantized using a quantization parameter QP. Selection of the quantization parameter QP is controlled by the control manager **160** via control line **115**.

In more detail, quantization of the DCT coefficients is performed by dividing each coefficient value by the quantization parameter QP and rounding the result to the nearest integer. In this way the quantization process yields a set of quantized DCT coefficient values that have a reduced numerical precision compared with the coefficient values originally generated by DCT transformation block **104**. Thus, in general, each of the quantized DCT coefficients may be represented by a smaller number of data bits than required to represent the corresponding coefficient before quantization. Furthermore, certain DCT coefficients are reduced to zero by the quantization process, thus reducing the number of coefficients that must be coded. Both these effects result in a reduction in the amount of data (i.e. data bits) required to represent the DCT coefficients for an image block. Thus, quantization provides a further mechanism by which the amount of data required to represent each image of the video sequence can be reduced. It also introduces an irreversible loss of information, which leads to a corresponding reduction in image quality. While this reduction in image quality may not always be desirable, quantization of DCT coefficient values does provide the possibility to adjust the number of bits required to encode a video sequence to take into account e.g. the bandwidth available for transmission of the encoded sequence or the desired quality of the coded video. More specifically, by increasing the value of QP used to quantize the DCT coefficients, a lower quality, but more compact representation of the video sequence can be created. Conversely, by reducing the value of QP, a higher quality but less compressed encoded bit-stream can be formed.

The quantized DCT coefficients for each block are passed from the quantizer **106** to the video multiplex coder **170**, as indicated by line **125** in FIG. 1. The video multiplex coder **170** orders the quantized transform coefficients for each block using a zigzag scanning procedure, thereby converting the

two-dimensional array of quantized transform coefficient values into a one-dimensional array. Typically, the video multiplex coder **170** next represents each non-zero quantized coefficient in the one-dimensional array by a pair of values, referred to as level and run, level being the value of the quantized coefficient and run being the number of consecutive zero-valued coefficients preceding the coefficient in question. The run and level values are further compressed using entropy coding. For example, a method such as variable length coding (VLC) may be used to produce a set of variable length codewords representative of each (run, level) pair.

Once the (run, level) pairs have been entropy (e.g. variable length) coded, the video multiplex coder **170** further combines them with control information, also entropy coded, for example, using a variable length coding method appropriate for the kind of information in question, to form a single compressed bit-stream of coded image information **135**. It is this bit-stream, including the variable length codewords representative of the (run, level) pairs and control information relating, among other things, to the quantization parameter QP used for quantizing the DCT coefficients, which is transmitted from the encoder.

A locally decoded version of the macroblock is also formed in the encoder **100**. This is done by passing the quantized transform coefficients for each block, output by quantizer **106**, through inverse quantizer **108** and applying an inverse DCT transform in inverse transformation block **110**. Inverse quantization is performed by reversing the quantization operation performed in quantizer **106**. More specifically, inverse quantizer **108** attempts to recover the original DCT coefficient values for a given image block by multiplying each quantized DCT coefficient value by quantization parameter QP. Because of the rounding operation performed as part of the quantization process in quantizer **106**, it is generally not possible to recover the original DCT coefficient values exactly. This results in a discrepancy between the recovered DCT coefficient values and those originally produced by DCT transformation block **104** (hence the irreversible loss of information referred to above).

The operations performed by inverse quantizer **108** and inverse transformation block **110** yield a reconstructed array of pixel values for each block of the macroblock. The resulting decoded image data is input to combiner **112**. In INTRA-coding mode, switch **114** is set so that the input to the combiner **112** via switch **114** is zero. In this way, the operation performed by combiner **112** is equivalent to passing the decoded image data unaltered.

As subsequent macroblocks of the current frame are received and undergo the previously described encoding and local decoding steps in blocks **104**, **106**, **108**, **110** and **112**, a decoded version of the INTRA-coded frame is built up in frame store **120**. When the last macroblock of the current frame has been INTRA-coded and subsequently decoded, the frame store **120** contains a completely decoded frame, available for use as a prediction reference frame in coding a subsequently received video frame in INTER-coded format. The flag indicating INTRA or INTER-code format is provided in line **122**.

Operation of the encoder **100** in INTER-coding mode will now be described. In INTER-coding mode, the control manager **160** operates switch **102** to receive its input from line **117**, which comprises the output of combiner **116**. The combiner **116** receives the video input signal macroblock by macroblock from input **101**. As combiner **116** receives the blocks of luminance and chrominance values which make up the macroblock, it forms corresponding blocks of prediction error information. The prediction error information repre-

sents the difference between the block in question and its prediction, produced in motion compensated prediction block **150**. More specifically, the prediction error information for each block of the macroblock comprises a two-dimensional array of values, each of which represents the difference between a pixel value in the block of luminance or chrominance information being coded and a decoded pixel value obtained by forming a motion-compensated prediction for the block, according to the procedure described below.

The prediction error information for each block of the macroblock is passed to DCT transformation block **104**, which performs a two-dimensional discrete cosine transform on each block of prediction error values to produce a two-dimensional array of DCT transform coefficients for each block.

The transform coefficients for each prediction error block are passed to quantizer **106** where they are quantized using a quantization parameter QP, in a manner analogous to that described above in connection with operation of the encoder in INTRA-coding mode. Again, selection of the quantization parameter QP is controlled by the control manager **160** via control line **115**. The accuracy of prediction error coding can be adjusted depending on the available bandwidth and/or required quality of the coded video. In a typical Discrete Cosine Transform (DCT) based system this is done by varying the Quantizer Parameter (QP) used in quantizing the DCT coefficients the DCT coefficients to a specific accuracy.

The quantized DCT coefficients representing the prediction error information for each block of the macroblock are passed from quantizer **106** to video multiplex coder **170**, as indicated by line **125** in FIG. 1. As in INTRA-coding mode, the video multiplex coder **170** orders the transform coefficients for each prediction error block using a zigzag scanning procedure and then represents each non-zero quantized coefficient as a (run, level) pair. It further compresses the (run, level) pairs using entropy coding, in a manner analogous to that described above in connection with INTRA-coding mode. Video multiplex coder **170** also receives motion vector information (described in the following) from motion field coding block **140** via line **126** and control information (e.g. including an indication of the quantization parameter QP) from control manager **160**. It entropy codes the motion vector information and control information and forms a single bit-stream of coded image information, **135** comprising the entropy coded motion vector, prediction error and control information. The indication, qz, of the quantization parameter QP is provided to multiplex coder **170** via line **124**.

The quantized DCT coefficients representing the prediction error information for each block of the macroblock are also passed from quantizer **106** to inverse quantizer **108**. Here they are inverse quantized, in a manner analogous to that previously described in connection with operation of the encoder in INTRA-coding mode. In INTER-coding mode, the quality of the encoded video bit-stream and the number of bits required to represent the video sequence can be adjusted by varying the degree of quantization applied to the DCT coefficients representing the prediction error information.

The resulting blocks of inverse quantized DCT coefficients are applied to inverse DCT transform block **110**, where they undergo inverse DCT transformation to produce locally decoded blocks of prediction error values. The locally decoded blocks of prediction error values are then input to combiner **112**. In INTER-coding mode, switch **114** is set so that the combiner **112** also receives predicted pixel values for each block of the macroblock, generated by motion-compensated prediction block **150**. The combiner **112** combines each of the locally decoded blocks of prediction error values with

a corresponding block of predicted pixel values to produce reconstructed image blocks and stores them in frame store **120**.

As subsequent macroblocks of the video signal are received from the video source and undergo the previously described encoding and decoding steps in blocks **104**, **106**, **108**, **110**, **112**, a decoded version of the frame is built up in frame store **120**. When the last macroblock of the frame has been processed, the frame store **120** contains a completely decoded frame, available for use as a prediction reference frame in encoding a subsequently received video frame in INTER-coded format.

Formation of a prediction for a macroblock of the current frame will now be described. Any frame encoded in INTER-coded format requires a reference frame for motion-compensated prediction. This means, necessarily, that when encoding a video sequence, the first frame to be encoded, whether it is the first frame in the sequence, or some other frame, must be encoded in INTRA-coded format. This, in turn, means that when the video encoder **100** is switched into INTER-coding mode by control manager **160**, a complete reference frame, formed by locally decoding a previously encoded frame, is already available in the frame store **120** of the encoder. In general, the reference frame is formed by locally decoding either an INTRA-coded frame or an INTER-coded frame.

The first step in forming a prediction for a macroblock of the current frame is performed by motion estimation block **130**. The motion estimation block **130** receives the blocks of luminance and chrominance values which make up the current macroblock of the frame to be coded via line **128**. It then performs a block matching operation in order to identify a region in the reference frame which corresponds substantially with the current macroblock. In order to perform the block matching operation, motion estimation block accesses reference frame data stored in frame store **120** via line **127**. More specifically, motion estimation block **130** performs block-matching by calculating difference values (e.g. sums of absolute differences) representing the difference in pixel values between the macroblock under examination and candidate best-matching regions of pixels from a reference frame stored in the frame store **120**. A difference value is produced for candidate regions at all possible positions within a predefined search region of the reference frame and motion estimation block **130** determines the smallest calculated difference value. The offset between the macroblock in the current frame and the candidate block of pixel values in the reference frame that yields the smallest difference value defines the motion vector for the macroblock in question.

Once the motion estimation block **130** has produced a motion vector for the macroblock, it outputs the motion vector to the motion field coding block **140**. The motion field coding block **140** approximates the motion vector received from motion estimation block **130** using a motion model comprising a set of basis functions and motion coefficients. More specifically, the motion field coding block **140** represents the motion vector as a set of motion coefficient values which, when multiplied by the basis functions, form an approximation of the motion vector. Typically, a translational motion model having only two motion coefficients and basis functions is used, but motion models of greater complexity may also be used.

The motion coefficients are passed from motion field coding block **140** to motion compensated prediction block **150**. Motion compensated prediction block **150** also receives the best-matching candidate region of pixel values identified by motion estimation block **130** from frame store **120**. Using the approximate representation of the motion vector generated by

motion field coding block **140** and the pixel values of the best-matching candidate region from the reference frame, motion compensated prediction block **150** generates an array of predicted pixel values for each block of the macroblock. Each block of predicted pixel values is passed to combiner **116** where the predicted pixel values are subtracted from the actual (input) pixel values in the corresponding block of the current macroblock, thereby forming a set of prediction error blocks for the macroblock.

Operation of the video decoder **200**, shown in FIG. 2 will now be described. The decoder **200** comprises a video multiplex decoder **270**, which receives an encoded video bit-stream **135** from the encoder **100** and demultiplexes it into its constituent parts, an inverse quantizer **210**, an inverse DCT transformer **220**, a motion compensated prediction block **240**, a frame store **250**, a combiner **230**, a control manager **260**, and an output **280**.

The control manager **260** controls the operation of the decoder **200** in response to whether an INTRA- or an INTER-coded frame is being decoded. An INTRA/INTER trigger control signal, which causes the decoder to switch between decoding modes is derived, for example, from picture type information associated with each compressed video frame received from the encoder. The INTRA/INTER trigger control signal is extracted from the encoded video bit-stream by the video multiplex decoder **270** and is passed to control manager **260** via control line **215**.

Decoding of an INTRA-coded frame is performed macroblock-by-macroblock. The video multiplex decoder **270** separates the encoded information for the blocks of the macroblock from possible control information relating to the macroblock in question. The encoded information for each block of an INTRA-coded macroblock comprises variable length codewords representing the VLC coded level and run values for the non-zero quantized DCT coefficients of the block. The video multiplex decoder **270** decodes the variable length codewords using a variable length decoding method corresponding to the encoding method used in the encoder **100** and thereby recovers the (run, level) pairs. It then reconstructs the array of quantized transform coefficient values for each block of the macroblock and passes them to inverse quantizer **210**. Any control information relating to the macroblock is also decoded in the video multiplex decoder using an appropriate decoding method and is passed to control manager **260**. In particular, information relating to the level of quantization applied to the transform coefficients (i.e. quantization parameter QP) is extracted from the encoded bit-stream by video multiplex decoder **270** and provided to control manager **260** via control line **217**. The control manager, in turn, conveys this information to inverse quantizer **210** via control line **218**. Inverse quantizer **210** inverse quantizes the quantized DCT coefficients for each block of the macroblock according to the control information relating to quantization parameter QP and provides the now inverse quantized DCT coefficients to inverse DCT transformer **220**. The inverse quantization operation performed by inverse quantizer **210** is identical to that performed by inverse quantizer **108** in the encoder.

Inverse DCT transformer **220** performs an inverse DCT transform on the inverse quantized DCT coefficients for each block of the macroblock to form a decoded block of image information comprising reconstructed pixel values. The reconstructed pixel values for each block of the macroblock are passed via combiner **230** to the video output **280** of the decoder where, for example, they can be provided to a display device (not shown). The reconstructed pixel values for each block of the macroblock are also stored in frame store **250**.

Because motion-compensated prediction is not used in the encoding/decoding of INTRA coded macroblocks control manager **260** controls combiner **230** to pass each block of pixel values as such to the video output **280** and frame store **250**. As subsequent macroblocks of the INTRA-coded frame are decoded and stored, a decoded frame is progressively assembled in the frame store **250** and thus becomes available for use as a reference frame for motion compensated prediction in connection with the decoding of subsequently received INTER-coded frames.

INTER-coded frames are also decoded macroblock by macroblock. The video multiplex decoder **270** receives the encoded video bit-stream **135** and separates the encoded prediction error information for each block of an INTER-coded macroblock from encoded motion vector information and possible control information relating to the macroblock in question. As explained in the foregoing, the encoded prediction error information for each block of the macroblock typically comprises variable length codewords representing the level and run values for the non-zero quantized transform coefficients of the prediction error block in question. The video multiplex decoder **270** decodes the variable length codewords using a variable length decoding method corresponding to the encoding method used in the encoder **100** and thereby recovers the (run, level) pairs. It then reconstructs an array of quantized transform coefficient values for each prediction error block and passes them to inverse quantizer **210**. Control information relating to the INTER-coded macroblock is also decoded in the video multiplex decoder **270** using an appropriate decoding method and is passed to control manager **260**. Information relating to the level of quantization (QP) applied to the transform coefficients of the prediction error blocks is extracted from the encoded bit-stream and provided to control manager **260** via control line **217**. The control manager, in turn, conveys this information to inverse quantizer **210** via control line **218**. Inverse quantizer **210** inverse quantizes the quantized DCT coefficients representing the prediction error information for each block of the macroblock according to the control information relating to quantization parameter QP and provides the now inverse quantized DCT coefficients to inverse DCT transformer **220**. Again, the inverse quantization operation performed by inverse quantizer **210** is identical to that performed by inverse quantizer **108** in the encoder. The INTRA/INTER flag is provided in line **215**.

The inverse quantized DCT coefficients representing the prediction error information for each block are then inverse transformed in the inverse DCT transformer **220** to yield an array of reconstructed prediction error values for each block of the macroblock.

The encoded motion vector information associated with the macroblock is extracted from the encoded video bit-stream **135** by video multiplex decoder **270** and is decoded. The decoded motion vector information thus obtained is passed via control line **225** to motion compensated prediction block **240**, which reconstructs a motion vector for the macroblock using the same motion model as that used to encode the INTER-coded macroblock in encoder **100**. The reconstructed motion vector approximates the motion vector originally determined by motion estimation block **130** of the encoder. The motion compensated prediction block **240** of the decoder uses the reconstructed motion vector to identify the location of a region of reconstructed pixels in a prediction reference frame stored in frame store **250**. The region of pixels indicated by the reconstructed motion vector is used to form a prediction for the macroblock in question. More specifically, the motion compensated prediction block **240** forms

an array of pixel values for each block of the macroblock by copying corresponding pixel values from the region of pixels identified in the reference frame. These blocks of pixel values, derived from the reference frame, are passed from motion compensated prediction block **240** to combiner **230** where they are combined with the decoded prediction error information. In practice, the pixel values of each predicted block are added to corresponding reconstructed prediction error values output by inverse DCT transformer **220**. In this way, an array of reconstructed pixel values for each block of the macroblock is obtained. The reconstructed pixel values are passed to the video output **280** of the decoder and are also stored in frame store **250**.

As subsequent macroblocks of the INTER-coded frame are decoded and stored, a decoded frame is progressively assembled in the frame store **250** and thus becomes available for use as a reference frame for motion-compensated prediction of other INTER-coded frames.

As described above, typical video encoding and decoding systems (commonly referred to as video codecs) are based on motion compensated prediction and prediction error coding. Motion compensated prediction is obtained by analyzing and coding motion between video frames and reconstructing image segments using the motion information. Prediction error coding is used to code the difference between motion compensated image segments and corresponding segments of the original image. The accuracy of prediction error coding can be adjusted depending on the available bandwidth and required quality of the coded video. In a typical Discrete Cosine Transform (DCT) based system this is done by varying the quantization parameter (QP) used in quantizing the DCT coefficients to a specific accuracy.

It should be noted that, in order to stay in synchronization with the encoder, the decoder has to know the exact value of the QP used in the coded video sequence. Typically, the QP value is transmitted once per slice leading to increase in the number of bits needed to encode the image. (As previously explained, a slice contains part of the image and is coded independently from other slices in order to avoid propagation of possible transmission errors inside the picture). For example, if the coding of a single QP value takes 6 bits and 20 images, each divided into 10 slices, are transmitted every second, 1.2 kbps is spent for the QP information alone.

Prior art solutions (for example, the H.26L video coding recommendation presented in the document by T. Wiegand, "Joint Model Number 1", Doc. JVT-A003, Joint Video Team (JVT) of ISO/IEC MPEG and ITU-T VCEG, January 2002) code the picture/slice QP parameters independently with a fixed or variable length code. This leads to increased transmission bit-rate as described above. More specifically, according to H.26L Joint Model Number 1, the quantization parameter value QP used in quantizing the DCT coefficient values is typically indicated in the encoded bit-stream at the beginning of each picture (see T. Wiegand, "Joint Model Number 1", Doc. JVT-A003, Joint Video Team (JVT) of ISO/IEC MPEG and ITU-T VCEG, January 2002, Section 3.3.1). If the macroblocks within a frame are arranged in slices then the QP value is also indicated at the beginning of each slice of the frame (e.g. in an optional slice header portion of the encoded bit-stream). In both cases, the QP value is indicated as such or is coded using an appropriate variable length coding scheme. As stated above, it should be realized that this scheme is very costly in terms of the number of bits required to represent the quantization parameter information, particularly in situations where frames are divided into many slices and/or the available bandwidth available for transmission of the encoded video sequence is low. This is a particu-

larly significant problem in mobile video applications in which the encoded video bit-stream is transmitted over a radio communications link. In this situation, the bandwidth available for transmission of the encoded video bit-stream may be as low as 20 kbits/s and the QP information included in the bit-stream may represent a significant proportion of the overall available bandwidth.

Furthermore, according to H.26L, the value of QP may optionally be varied at the macroblock level by inserting a quantizer change parameter (Dquant) in the portion of the encoded bit-stream representative of the macroblock in question (see T. Wiegand, "Joint Model Number 1", Doc. JVT-A003, Joint Video Team (JVT) of ISO/IEC MPEG and ITU-T VCEG, January 2002, Section 3.4.7). This leads to a further increase in the amount of information in the encoded bit-stream that is devoted to the indication of QP related information.

In view of the foregoing, it should be realised that there is a significant need for an improved mechanism for indicating information relating to quantization parameter values in video coding systems.

SUMMARY OF THE INVENTION

The present invention improves prior art solutions for indicating QP related information by introducing a sequence level QP. This allows the encoder application to decide a video sequence dependent reference QP to be used in coding of the picture/slice QPs. Now, according to the invention, instead of coding the absolute values of picture/slice QPs, it is enough to code the difference between the reference sequence QP and the actually used picture/slice QP. In this way there is no need to transmit a full QP for every picture/slice, but a statistically smaller difference value is transmitted and used to reconstruct the picture/slice QP, thus leading to reduction in transmission bit-rate.

The bit-rate savings are most evident in the case of constant QP. In this case, it is sufficient to send just one bit per slice to indicate that the sequence QP is to be used when decoding the slice. For example, in the previously described example, the bit-rate for QP is reduced from 1.2 kbps to 0.2 kbps (now only one bit needs to be sent instead of six for each slice).

According to a first aspect of the invention, there is provided a method of encoding a digital video sequence, the method being applied in a video coding application to produce an encoded video bit-stream representative of the digital video sequence. The digital video sequence comprises a number of frames, each frame of the sequence comprising an array of pixels and is divided into a plurality of blocks, each block comprising a certain number of pixels. The method comprises encoding a frame of the digital video sequence by applying motion compensated prediction to blocks of pixels, thereby producing corresponding blocks of prediction error values. A transform coding technique is applied to the blocks of prediction error values to produce sets of transform coefficient values representative of the blocks of prediction error values and a level of quantization is applied to the sets of transform coefficient values to yield sets of quantized transform coefficient values. According to the invention, the method further comprises defining a default level of quantization to be used throughout encoding of the digital video sequence to quantize the sets of transform coefficient values.

Advantageously, the method according to the first aspect of the invention is also used to indicate quantization parameter (QP) values used to quantize sets of transform coefficient values representative of blocks of pixel values produced for frames coded in INTRA-coding mode in a manner analogous

to that described above for indicating the quantization parameter values used to quantize sets of transform coefficient values representative of prediction error values produced for frames coded in INTER-coding mode.

Advantageously, the default level of quantization to be used throughout encoding of the digital video sequence is specific to the video sequence being encoded. Alternatively, the default level of quantization is specific to the video coding application.

Preferably, an indication of the default level of quantization to be used throughout encoding of the digital video sequence is provided. Even more preferably, an indication of the default level of quantization is provided in the encoded bit-stream representative of the digital video sequence, advantageously, the encoded bit-stream, including the indication of the default level of quantization to be used throughout encoding of the digital video sequence, is transmitted to a video decoding device.

Advantageously, the default level of quantization to be used throughout encoding of the digital video sequence to quantize the sets of transform coefficient values can be updated during encoding of the digital video sequence and a further indication indicative of the updated default level of quantization is provided.

The indication of the updated default level of quantization is preferably transmitted to a video decoding device, advantageously, in the encoded bit-stream representative of the digital video sequence.

Advantageously, the level of quantization applied to said sets of transform coefficient values can be adjusted such that the actual level of quantization applied to the sets of transform coefficient values is different from the default level of quantization to be used throughout encoding of the video sequence. Preferably, the actual level of quantization applied is represented as a difference with respect to the default level of quantization. Advantageously, an indication of the difference with respect to the default level of quantization is provided in the encoded bit-stream representative of the digital video sequence.

In an embodiment of the video encoding method according to the first aspect of the invention, the level of quantization applied to the sets of transform coefficient values can be adjusted from one frame of the digital video sequence to another such that an actual level of quantization applied to the sets of transform coefficients for a particular frame of the digital video sequence is different from the default level of quantization to be used throughout encoding of the digital video sequence. Advantageously, in this embodiment, the actual level of quantization to be used in the particular frame is represented as a difference with respect to the default level of quantization and an indication of the difference with respect to the default level of quantization is provided in the encoded bit-stream representative of the digital video sequence.

In an alternative embodiment of the video encoding method according to the first aspect of the invention, the plurality of blocks into which a frame of the digital video sequence is divided are grouped into one or more segments and the level of quantization applied to the sets of transform coefficient values can be adjusted from one segment of a frame to another such that an actual level of quantization applied to the sets of transform coefficients for a particular segment of a frame is different from the default level of quantization to be used throughout encoding of the digital video sequence. Advantageously, in this alternative embodiment, the actual level of quantization to be used in the particular segment is represented as a difference with respect to

13

the default level of quantization and an indication of the difference with respect to the default level of quantization is provided in the encoded bit-stream representative of the digital video sequence.

Advantageously, if the default level of quantization is to be used to quantize all sets of transform coefficient values throughout the digital video sequence, an indication of the default level of quantization is provided together with an indication that said default level is to be used to quantize all sets of transform coefficient values throughout the digital video sequence.

According to a second aspect of the invention, there is provided a method of decoding an encoded digital video sequence, the method being applied in a video decoding application to produce a decoded digital video sequence. The digital video sequence comprises a number of frames, each frame of the sequence comprising an array of pixels and being divided into a plurality of blocks, each block comprising a certain number of pixels, frames of the digital video sequence having been encoded by applying motion compensated prediction to blocks of pixels to produce corresponding blocks of prediction error values and applying a transform coding technique to the blocks of prediction error values to produce sets of transform coefficient values representative of the blocks of prediction error values and applying a level of quantization to the sets of transform coefficient values to yield sets of quantized transform coefficient values representative of the blocks of prediction error values. According to the invention, the decoding method comprises defining a default level of inverse quantization to be used throughout decoding of the encoded digital video sequence to inverse quantize the sets of quantized transform coefficient values.

Advantageously, the default level of inverse quantization is identical to a default level of quantization used to quantize the sets of transform coefficient values during encoding of the video sequence.

Advantageously, the default level of inverse quantization defined to be used throughout decoding of the encoded digital video sequence is specific to the encoded video sequence being decoded. Alternatively, the default level of inverse quantization is specific to the video decoding application.

Advantageously, the decoding method comprises retrieving an indication of the default level of inverse quantization, preferably from a bit-stream representative of the encoded digital video sequence.

Advantageously, the default level of inverse quantization can be updated during decoding of the digital video sequence. Preferably, updating of the default level of inverse quantization is performed responsive to an indication of an updated default level of quantization used during encoding of the video sequence, retrieved from a bit-stream representative of the encoded digital video sequence. Alternatively, the default level of inverse quantization is updated responsive to an indication of an updated default level of quantization used during encoding of the video sequence, transmitted from a video encoding device.

Advantageously, the level of inverse quantization applied to the sets of quantized transform coefficient values can be adjusted such that an actual level of inverse quantization applied to the sets of quantized transform coefficient values is different from the default level of inverse quantization to be used throughout decoding of the encoded digital video sequence. In this case, the actual level of inverse quantization is determined by adding a difference value to the default level of inverse quantization, the difference value being representative of the difference between the default level of inverse quantization and the actual level of inverse quantization to be

14

applied. Preferably, an indication of the difference value is retrieved from a bit-stream representative of the encoded digital video sequence.

In an embodiment of the video decoding method according to the second aspect of the invention, the level of inverse quantization applied to the sets of quantized transform coefficient values is adjusted from one frame of the digital video sequence to another such that an actual level of inverse quantization applied to the sets of quantized transform coefficients for a particular frame of the digital video sequence is different from the default level of inverse quantization to be used throughout decoding of the encoded digital video sequence. Advantageously, in this embodiment, the actual level of inverse quantization to be used in the particular frame is determined by adding a frame-specific difference value to the default level of inverse quantization, the frame-specific difference value being representative of the difference between the default level of inverse quantization and the actual level of inverse quantization to be used in the particular frame. Preferably, an indication of said frame-specific difference value is retrieved from a bit-stream representative of the encoded digital video sequence.

In an alternative embodiment of the video decoding method according to the second aspect of the invention, the plurality of blocks into which a frame of said digital video sequence is divided are grouped into one or more segments and the level of inverse quantization applied to the sets of quantized transform coefficient values is adjusted from one segment of a frame to another such that an actual level of inverse quantization applied to the sets of quantized transform coefficients for a particular segment of a frame is different from the default level of inverse quantization to be used throughout decoding of the encoded digital video sequence. Advantageously, in this alternative embodiment, the actual level of inverse quantization to be used in the particular segment is determined by adding a segment-specific difference value to the default level of inverse quantization, the segment-specific difference value being representative of the difference between the default level of inverse quantization and the actual level of inverse quantization to be used in the particular segment. Preferably, an indication of the segment-specific difference value is retrieved from a bit-stream representative of the encoded digital video sequence.

According to a third aspect of the invention, there is provided an encoder for encoding a digital video sequence to produce an encoded video bit-stream representative of the digital video sequence, the digital video sequence comprising a number of frames, each frame of the sequence comprising an array of pixels and being divided into a plurality of blocks, each block comprising a certain number of pixels. The video encoder according to the third aspect of the invention is arranged to encode a frame of the digital video sequence by applying motion compensated prediction to blocks of pixels, thereby producing corresponding blocks of prediction error values. It is further arranged to apply a transform coding technique to blocks of prediction error values to produce sets of transform coefficient values representative of said blocks of prediction error values and to apply a level of quantization to said sets of transform coefficient values to yield sets of quantized transform coefficient values. According to the invention, the video encoder is further arranged to define a default level of quantization to be used throughout encoding of the digital video sequence to quantize the sets of transform coefficient values.

Advantageously, the encoder according to the third aspect of the invention is also arranged to indicate quantization parameter (QP) values used to quantize sets of transform

15

coefficient values representative of blocks of pixel values produced for frames coded in INTRA-coding mode in a manner analogous to that described above for indicating the quantization parameter values used to quantize sets of transform coefficient values representative of prediction error values produced for frames coded in INTER-coding mode.

Advantageously, the default level of quantization defined by the video encoder is specific to the video sequence being encoded.

Advantageously, the video encoder is further arranged to provide an indication of the default level of quantization in the encoded bit-stream representative of the digital video sequence. Even more advantageously, it is arranged to transmit the encoded bit-stream to a corresponding video decoder.

Advantageously the video encoder is further arranged to update the default level of quantization during encoding of the digital video sequence and to provide an indication of the updated default level of quantization. Preferably, the encoder is also arranged to transmit the indication of the updated default level of quantization to a corresponding video decoder. Advantageously, the encoder includes the indication of the updated default level of quantization in the encoded bit-stream representative of the digital video sequence.

Preferably, the video encoder is further arranged to adjust the level of quantization applied to the sets of transform coefficient values and thereby to apply an actual level of quantization that is different from the default level of quantization. Preferably, the video encoder is still further arranged to represent the actual level of quantization as a difference with respect to the default level of quantization and to provide an indication of the difference with respect to the default level of quantization in the encoded bit-stream representative of the digital video sequence.

In one embodiment, a video encoder according to the third aspect of the invention is arranged to adjust the level of quantization applied to the sets of transform coefficient values from one frame of the digital video sequence to another. In this way it is arranged to apply an actual level of quantization to the sets of transform coefficients for a particular frame that is different from the default level of quantization to be used throughout encoding of the digital video sequence. Advantageously, the video encoder according to this embodiment is further arranged to represent the actual level of quantization to be used in the particular frame as a difference with respect to the default level of quantization and to provide an indication of the difference with respect to the default level of quantization in the encoded bit-stream representative of the digital video sequence.

In an alternative embodiment, a video encoder according to the third aspect of the invention is further arranged to group the plurality of blocks into which a frame of the digital video sequence is divided into one or more segments and to adjust the level of quantization applied to the sets of transform coefficient values from one segment of a frame to another. In this way the video encoder is arranged to apply an actual level of quantization to the sets of transform coefficients for a particular segment of a frame that is different from the default level of quantization to be used throughout encoding of the digital video sequence. Advantageously, the video encoder according to this alternative embodiment is further arranged to represent the actual level of quantization to be used in the particular segment as a difference with respect to the default level of quantization and to provide an indication of the difference with respect to the default level of quantization in the encoded bit-stream representative of the digital video sequence.

16

In a particular embodiment, the video encoder is arranged to provide an indication of the default level of quantization and an indication that the default level is to be used to quantize all sets of transform coefficient values throughout the digital video sequence.

Advantageously, the video encoder according to the third aspect of the invention is provided in a multimedia terminal. Even more preferably, it is implemented in a radio telecommunications device.

According to a fourth aspect of the invention, there is provided a decoder for decoding an encoded digital video sequence to produce a decoded digital video sequence. The digital video sequence comprises a number of frames, each frame of the sequence comprising an array of pixels and being divided into a plurality of blocks, each block comprising a certain number of pixels, frames of the digital video sequence having been encoded by applying motion compensated prediction to blocks of pixels to produce corresponding blocks of prediction error values and applying a transform coding technique to the blocks of prediction error values to produce sets of transform coefficient values representative of said blocks of prediction error values and applying a level of quantization to the sets of transform coefficient values to yield sets of quantized transform coefficient values representative of the blocks of prediction error values. According to the invention, the video decoder is arranged to define a default level of inverse quantization to be used throughout decoding of the encoded digital video sequence to inverse quantize the sets of quantized transform coefficient values.

Preferably, the default level of inverse quantization is identical to a default level of quantization used to quantize the sets of transform coefficient values during encoding of the video sequence.

Advantageously, the default level of inverse quantization defined to be used throughout decoding of the encoded digital video sequence is specific to the encoded video sequence being decoded.

Advantageously, the video decoder is arranged to retrieve an indication of the default level of inverse quantization, preferably from a bit-stream representative of the encoded digital video sequence.

Advantageously, the video decoder is arranged to update the default level of inverse quantization during decoding of the digital video sequence, preferably by retrieving an indication of an updated default level of quantization from a bit-stream representative of the encoded digital video sequence. Alternatively, the video decoder is arranged to receive an indication of an updated default level of quantization transmitted from a video encoding device.

Preferably, the video decoder is arranged to adjust the level of inverse quantization applied to the sets of quantized transform coefficient values and to apply an actual level of inverse quantization to the sets of quantized transform coefficient values that is different from the default level of inverse quantization. Advantageously, the decoder is arranged to determine the actual level of inverse quantization by adding a difference value to the default level of inverse quantization, the difference value being representative of the difference between the default level of inverse quantization and the actual level of inverse quantization to be applied. Preferably, the video decoder is arranged to retrieve an indication of the difference value from a bit-stream representative of the encoded digital video sequence.

In one embodiment, a video decoder according to the fourth aspect of the invention is arranged to adjust the level of inverse quantization applied to the sets of quantized transform coefficient values from one frame of the digital video

17

sequence to another and to apply an actual level of inverse quantization to the sets of quantized transform coefficients for a particular frame of the digital video sequence that is different from the default level of inverse quantization to be used throughout decoding of the encoded digital video sequence. Advantageously, the decoder is arranged to determine the actual level of inverse quantization to be used in the particular frame by adding a frame-specific difference value to the default level of inverse quantization, the frame-specific difference value being representative of the difference between the default level of inverse quantization and the actual level of inverse quantization to be used in the particular frame. Preferably, the video decoder is arranged to retrieve an indication of the frame-specific difference value from a bit-stream representative of the encoded digital video sequence.

In an alternative embodiment, a video decoder according to the fourth aspect of the invention is arranged to decode an encoded video sequence in which the plurality of blocks into which a frame of said digital video sequence is divided are grouped into one or more segments and is further arranged to adjust the level of inverse quantization applied to the sets of quantized transform coefficient values from one segment of a frame to another and to apply an actual level of inverse quantization to the sets of quantized transform coefficients for a particular segment of a frame that is different from the default level of inverse quantization to be used throughout decoding of the encoded digital video sequence. Preferably, the decoder is arranged to determine the actual level of inverse quantization to be used in the particular segment by adding a segment-specific difference value to the default level of inverse quantization, the segment-specific difference value being representative of the difference between the default level of inverse quantization and the actual level of inverse quantization to be used in the particular segment. Preferably, the video decoder is arranged to retrieve an indication of the segment-specific difference value from a bit-stream representative of the encoded digital video sequence.

According to a fifth aspect of the invention, there is provided a multimedia terminal comprising an encoder according to the third aspect of the invention.

According to a sixth aspect of the invention, there is provided a multimedia terminal comprising a decoder according to the fourth aspect of the invention.

Preferably, the multimedia terminal according to the fifth and/or sixth aspects of the invention is a mobile multimedia terminal arranged to communicate with a mobile telecommunications network by means of a radio connection.

BRIEF DESCRIPTION OF THE DRAWINGS

FIG. 1 illustrates the formation of a 16×16 macroblock according to prior art.

FIG. 2 illustrates subdivision of a QCIF picture into 16×16 macroblocks and grouping of consecutive macroblocks into slices.

FIG. 3 is a schematic block diagram of a generic video encoder according to prior art.

FIG. 4 is a schematic block diagram of a generic video decoder according to prior art and corresponding to the encoder shown in FIG. 3.

FIG. 5 is a schematic block diagram of a video encoder according to an embodiment of the invention.

FIG. 6 is a schematic block diagram of a video decoder according to an embodiment of the invention and corresponding to the encoder shown in FIG. 5.

FIG. 7 illustrates a decoding process according to one possible embodiment of the invention. Quantization param-

18

eters (QP) for each slice are obtained by adding the Sequence QP (SQP) to slice specific difference QP values (ΔQP^n).

FIG. 8 is a schematic block diagram of a multimedia communications terminal in which the method according to the invention may be implemented.

DETAILED DESCRIPTION OF THE INVENTION

In a preferred embodiment of the invention a video sequence specific quantization parameter (QP) is transmitted and used as a reference when coding and decoding the actual picture/slice quantization parameters. In this way there is no need to transmit a full QP for every picture/slice, but a statistically smaller difference value is transmitted and used to reconstruct the picture/slice QP, thus leading to reduction in transmission bit-rate.

Embodiments of the invention will now be described with reference to FIGS. 5 through 8.

FIG. 5 is a schematic block diagram of a video encoder 600 implemented according to the preferred embodiment of the invention. The structure of the video encoder shown in FIG. 5 is substantially identical to that of the prior art video encoder illustrated in FIG. 3, with appropriate modifications to those parts of the encoder that perform operations relating to the quantization of DCT transform coefficients and the signalling of quantization parameter (QP) values used in the video encoding process. All parts of the video encoder that implement functions and operate in a manner identical to the previously described prior art video encoder are identified with identical reference numbers. As the invention is particularly relevant to the signalling of quantization parameter (QP) values at the slice or frame level, it will be assumed throughout the following description that video encoder 600 according to the preferred embodiment of the invention is specifically adapted to apply a video coding method in which the frames of a video sequence to be coded are divided into macroblocks and the macroblocks are further grouped into slices, an indication of the quantization parameter being provided at the beginning of each frame and at the beginning of each new slice within a frame. An example of such a video coding method is the previously cited ITU-T H.26L video coding recommendation, as described in T. Wiegand, "Joint Model Number 1", Doc. JVT-A003, Joint Video Team (JVT) of ISO/IEC MPEG and ITU-T VCEG, January 2002. Alternatively, the method can be applied in a video coding system in which an indication of the quantization parameter is given only at the beginning of a frame. While the following detailed description is written specifically to illustrate application of the method according to the invention in the indication and signalling of slice level quantization parameters, it should be appreciated that the method can be applied in an exactly analogous manner to the representation of frame (picture) level quantization parameters.

Operation of video encoder 600 will now be considered in detail. When encoding a digital video sequence, encoder 600 operates in a manner similar to that previously described in connection with FIG. 3 to generate INTRA-coded and INTER-coded compressed video frames. As explained earlier in the text, in INTRA-coding mode, a Discrete Cosine Transform (DCT) is applied to each block of image data (pixel values) in order to produce a corresponding two-dimensional array of transform coefficient values. The DCT operation is performed in transform block 104 and the coefficients thus produced are subsequently passed to quantizer 106, where they are quantized. In INTER-coding mode, the DCT transform performed in block 104 is applied to blocks of prediction

error values. The transform coefficients produced as a result of this operation are also passed to quantizer 106 where they too are quantized.

According to the invention, when starting to encode a new video sequence, encoder 600 determines a default or reference level of quantization that is to be used throughout encoding of the video sequence to quantize the DCT coefficient values generated in quantizer 106. Throughout the following description, this default or reference level of quantization will be termed a "sequence level quantization parameter", or SQP for short. The choice of an SQP for a given video sequence is controlled by control manager 660 and, for example, may be based on consideration of the properties of the sequence to be encoded and the bandwidth available for transmission of the encoded bit-stream produced by the encoder.

In the preferred embodiment of the invention, encoder 600 determines SQP as the default or reference level of quantization to be used when operating in INTER-coding mode, i.e. in situations when the DCT coefficients generated in transform block 104 are representative of prediction error values. It should be appreciated that the method according to the invention can also be applied to the quantization of DCT coefficient values produced in traditional INTRA-coding mode utilizing no spatial prediction. However, given the different origins of the transform coefficients in INTRA- and INTER-coding modes (the DCT coefficients produced in INTRA-coding mode are derived from pixel values, while those generated in INTER-coding mode are produced by applying a DCT transform to prediction error values) it is unlikely that a single SQP value can be determined that is optimum for quantization of DCT coefficients in both INTRA- and INTER-coding modes. Therefore, in an embodiment in which the method according to the invention is used in both INTRA- and INTER-coding mode, two SQP values are preferably be used, one that provides the most efficient representation of QP value information in INTRA-coding mode and another that provides the most efficient representation of QP values used during INTER-coding. In all other respects, the method according to the invention may be applied in a directly analogous way in both INTRA- and INTER-coding modes. Of course, in an alternative embodiment, a single SQP value may be defined and used as the sequence level quantization parameter for both INTRA- and INTER-coded frames. This is a practical approach especially in modern video coding systems, such as the one described in T. Wiegand, "Joint Model Number 1", Doc. JVT-A003, Joint Video Team (JVT) of ISO/IEC MPEG and ITU-T VCEG, January 2002, where spatial prediction is applied to the INTRA coded macroblocks before coding the INTRA prediction error with DCT.

It should further be noted that as the majority of frames in a typical video sequence are encoded as INTER frames, the greatest saving in bit-rate is achieved by applying the method according to the invention to the representation of QP values in INTER-coding mode. Thus, in the preferred embodiment of the invention, a single SQP value is used, this value being indicative of a default or reference value of quantization to be used in quantizing DCT coefficients representative of prediction error values in INTER-coding mode.

Having determined the SQP value to be used for the sequence, control manager 660 provides an indication of the selected SQP value via control line 122 to video multiplex coder 670 which, in turn, inserts an indication of the SQP value into the bit-stream 635 of coded image information representative of the video sequence. Preferably, this indication is provided in a sequence header portion of the encoded video bit-stream 635.

Video encoder 600 then starts to encode the video sequence. As explained in connection with the description of prior art video encoder 100, illustrated in FIG. 3, the first frame of the sequence to be encoded is encoded in INTRA-format. As the SQP value defined according to the preferred embodiment of the invention is specific to the quantization of DCT coefficient values produced in INTER-coding mode, operation of encoder 600 in INTRA-coding mode is entirely analogous to that of prior art video encoder 100 and will not be considered in further detail here.

Once encoding of the first frame is complete, control manager 660 switches video encoder 600 into INTER-coding mode. In INTER-coding mode, switch 102 is operated to receive its input from line 117, which comprises the output of combiner 116. Combiner 116 receives the video input signal macroblock by macroblock from input 101 and forms a block of prediction error information for each block of the macroblock. The prediction error information for each block is passed to DCT transformer 104, which performs a two-dimensional discrete cosine transform on each block of prediction error values to produce a two-dimensional array of DCT transform coefficients for the block in question. The transform coefficients for each prediction error block are then passed to quantizer 106 where they are quantized, as previously described, using a quantization parameter QP. The rest of the INTER-coding process continues as previously described in connection with prior art video encoder 100.

As each macroblock is received, control manager 660 determines whether the macroblock currently being processed is the first macroblock of a slice. If it is, the control manager determines a quantization parameter value QP to be used in quantizing the DCT coefficient values generated in DCT transformer 104. It should be noted that it is possible to make an estimation about the QP based on the bit-budget allowed for the frame, bits already spent in the previous slices or the same frame and possibly the bits spent for slices in the previous frame. Having done this, control manager 660 determines a difference (ΔQP) between the previously defined sequence level quantization parameter value SQP and the actual QP value to be used for the slice in question. It then passes an indication of this difference via control line 624 to video multiplex coder 670, which further includes an indication of the difference value ΔQP in bit-stream 635. Preferably, this indication is provided in a slice header portion of the encoded video bit-stream 635 containing control information specific to the slice in question. This process is repeated until all slices of the current frame have been encoded in INTER-coded format, at which point the video encoder starts to encode the next frame of the video sequence.

A video decoder 700 implemented according to a preferred embodiment of the invention will now be described with reference to FIG. 6. The structure of the video decoder illustrated in FIG. 6 is substantially identical to that of the prior art video decoder shown in FIG. 4, with appropriate modifications to those parts of the decoder that perform operations relating to the inverse quantization of DCT transform coefficients. All parts of the video decoder that implement functions and operate in a manner identical to the previously described prior art video decoder are identified with identical reference numbers.

Here it is assumed that the video decoder of FIG. 6 corresponds to the encoder described in connection with FIG. 5 and is therefore capable of receiving and decoding the bit-stream 635 transmitted by encoder 600. As previously described, in the preferred embodiment of the invention, encoder 600 determines a sequence level quantization parameter SQP to be used in INTER-coding mode. Correspond-

ingly, decoder **700** is adapted to receive an indication of this SQP value and to use the sequence level quantization parameter SQP in the determination of inverse quantization parameters to be applied to blocks of quantized transform coefficient values (representative of prediction error values) received in the encoded bit-stream for INTER-coded frames. In an alternative embodiment of the invention, the same process may also be applied to quantized transform coefficient values extracted from the bit-stream for INTRA-coded frames. As explained above, in this alternative embodiment, an indication of two SQP values may be provided, one for INTRA-coded frames of the sequence and one for INTER-coded frames. In a further alternative embodiment, a single sequence level quantization parameter may be indicated for frames coded in both INTRA- and INTER-coding modes.

Operation of a video decoder according to the preferred embodiment of the invention will now be described in detail. Decoder **700** receives bit-stream **635** and separates it into its constituent parts. This operation is performed by video multiplex decoder **770**.

When starting to decode a new sequence, video multiplex decoder **770** first extracts information and parameters relating to the sequence as a whole from the sequence header portion of the received bit-stream **635**. As explained above in connection with the description of encoder **600**, according to the preferred embodiment of the invention, the sequence header portion of the bit-stream is modified to contain an indication of the sequence level quantization parameter SQP used in quantization of DCT coefficient values produced in INTER-coding mode. Video multiplex decoder extracts the indication of the SQP value from the bit-stream and, if it was encoded, for example using variable length coding, applies appropriate decoding to recover the SQP value. It then passes the SQP value to the decoder's control manager **760**, which stores it in the decoder's memory.

Video decoder **700** then starts to decode the encoded frames of the video sequence, the decoding of each frame commencing as soon as the video decoder starts receiving information relating to the frame in video bit-stream **635**. Video multiplex decoder **770** extracts an INTRA/INTER trigger control signal from picture type information associated with each compressed video frame received in the encoded bit-stream **635** and passes it to control manager **760** via control line **215**. The control manager **760** controls the operation of the decoder responsive to the INTRA/INTER trigger control signal, so as to switch the decoder into the correct decoding mode.

In the preferred embodiment of the invention, the decoding of frames coded in INTRA-format is performed in a manner analogous to that previously described in connection with the operation of prior art video decoder **200**. The decoding of frames encoded in INTER-format, on the other hand, proceeds as described in the following.

When it receives an indication that the next frame to be decoded is an INTER-coded frame, extracted from the received bit-stream by video multiplex decoder **770**, control manager **760** switches decoder **700** into INTER-mode. As explained in connection with the description of encoder **600**, according to the preferred embodiment of the invention, in which the macroblocks of each frame are grouped into slices, encoded bit-stream **635** comprises certain slice-specific control information, which includes an indication of a slice-specific QP value, represented as a difference value ΔQP with respect to the sequence level quantization parameter SQP. Advantageously, the control information specifically related to each slice is provided in the bit-stream as a header portion specific to the slice in question. On receiving such a portion of

the bit-stream, video multiplex decoder extracts the slice-specific control information from the slice header portion of the bit-stream and passes the indication of ΔQP for the slice, retrieved from the bit-stream, to control manager **760** via control line **717**.

Next, control manager **760** determines a level of inverse quantization to be applied to the quantized DCT coefficients of the macroblocks in the slice. This is done by combining the ΔQP value for the slice with the sequence specific quantization parameter SQP, previously received and stored in the decoder's memory. As described earlier in the text, the inverse quantization operation performed in the decoder involves multiplying each quantized DCT coefficient by a value equal to the level of quantization originally applied, that is, by the QP value used in the corresponding encoder to quantize the DCT coefficients. Thus, according to the preferred embodiment of the invention, control manager **760** determines the level of inverse quantization for the macroblocks of the slice by adding the received ΔQP value for the slice to SQP. It then passes this value to inverse quantizer **210** via control line **218**.

As encoded information for each macroblock of the slice is received in the bit-stream **635**, video multiplex decoder **770** separates the encoded prediction error information for each block of the macroblock from encoded motion vector information. It reconstructs the quantized DCT transform coefficients representative of the prediction error values for each block and passes them to inverse quantizer **210**. Inverse quantizer **210** then inverse quantizes the quantized DCT coefficients according to the slice QP constructed from the ΔQP and SQP values by control manager **760**. It then provides the inverse quantized DCT coefficients to inverse DCT transformer **220**. The rest of the decoding process continues as previously described in connection with prior art video decoder **200**.

The steps of receiving a slice-specific ΔQP value, combining ΔQP with SQP and inverse quantizing the quantized DCT coefficients for each block of the macroblocks within the slice is repeated for each slice of the frame until all slices of the current INTER-coded frame have been decoded. At this point video encoder **700** starts decoding the next frame of the encoded video sequence.

FIG. 7 illustrates the way in which slice-specific QP values are reconstructed according to the preferred embodiment of the invention. As can be seen from the figure, the process comprises the steps of:

1. retrieving a sequence level quantization parameter (SQP);
2. retrieving a picture or slice level difference quantization parameter (ΔQP);
3. adding the difference quantization parameters to the sequence level quantization parameter to obtain the quantization parameters for a picture or a slice;
4. constructing the received prediction error-coding coefficients by means of said picture or slice quantization parameter.

FIG. 8 presents a terminal device comprising video encoding and decoding equipment which may be adapted to operate in accordance with the present invention. More precisely, the figure illustrates a multimedia terminal **80** implemented according to ITU-T recommendation H.324. The terminal can be regarded as a multimedia transceiver device. It includes elements that capture, encode and multiplex multimedia data streams for transmission via a communications network, as well as elements that receive, de-multiplex, decode and display received multimedia content. ITU-T recommendation H.324 defines the overall operation of the terminal and refers to other recommendations that govern the

23

operation of its various constituent parts. This kind of multimedia terminal can be used in real-time applications such as conversational videotelephony, or non real-time applications such as the retrieval and/or streaming of video clips, for example from a multimedia content server in the Internet.

In the context of the present invention, it should be appreciated that the H.324 terminal shown in FIG. 8 is only one of a number of alternative multimedia terminal implementations suited to application of the inventive method. It should also be noted that a number of alternatives exist relating to the location and implementation of the terminal equipment. As illustrated in FIG. 8, the multimedia terminal may be located in communications equipment connected to a fixed line telephone network such as an analogue PSTN (Public Switched Telephone Network). In this case the multimedia terminal is equipped with a modem 91, compliant with ITU-T recommendations V.8, V.34 and optionally V.8 bis. Alternatively, the multimedia terminal may be connected to an external modem. The modem enables conversion of the multiplexed digital data and control signals produced by the multimedia terminal into an analogue form suitable for transmission over the PSTN. It further enables the multimedia terminal to receive data and control signals in analogue form from the PSTN and to convert them into a digital data stream that can be demultiplexed and processed in an appropriate manner by the terminal.

An H.324 multimedia terminal may also be implemented in such a way that it can be connected directly to a digital fixed line network, such as an ISDN (Integrated Services Digital Network). In this case the modem 91 is replaced with an ISDN user-network interface. In FIG. 8, this ISDN user-network interface is represented by alternative block 92.

H.324 multimedia terminals may also be adapted for use in mobile communication applications. If used with a wireless communication link, the modem 91 can be replaced with any appropriate wireless interface, as represented by alternative block 93 in FIG. 8. For example, an H.324/M multimedia terminal can include a radio transceiver enabling connection to the current 2nd generation GSM mobile telephone network, or the proposed 3rd generation UMTS (Universal Mobile Telephone System).

It should be noted that in multimedia terminals designed for two-way communication, that is for transmission and reception of video data, it is advantageous to provide both a video encoder and video decoder implemented according to the present invention. Such an encoder and decoder pair is often implemented as a single combined functional unit, referred to as a "codec".

A typical H.324 multimedia terminal will now be described in further detail with reference to FIG. 8.

The multimedia terminal 80 includes a variety of elements referred to as "terminal equipment". This includes video, audio and telematic devices, denoted generically by reference numbers 81, 82 and 83, respectively. The video equipment 81 may include, for example, a video camera for capturing video images, a monitor for displaying received video content and optional video processing equipment. The audio equipment 82 typically includes a microphone, for example for capturing spoken messages, and a loudspeaker for reproducing received audio content. The audio equipment may also include additional audio processing units. The telematic equipment 83, may include a data terminal, keyboard, electronic whiteboard or a still image transceiver, such as a fax unit.

The video equipment 81 is coupled to a video codec 85. The video codec 85 comprises a video encoder 600 and a corresponding video decoder 700 both implemented according to the invention (see FIGS. 5 and 6). The video codec 85

24

is responsible for encoding captured video data in an appropriate form for further transmission over a communications link and decoding compressed video content received from the communications network. In the example illustrated in FIG. 8, the video codec is implemented according to ITU-T recommendation H.26L, with appropriate modifications to implement the method according to the invention in both the encoder and the decoder of the video codec.

The terminal's audio equipment is coupled to an audio codec, denoted in FIG. 8 by reference number 86. Like the video codec, the audio codec comprises an encoder/decoder pair. It converts audio data captured by the terminal's audio equipment into a form suitable for transmission over the communications link and transforms encoded audio data received from the network back into a form suitable for reproduction, for example on the terminal's loudspeaker. The output of the audio codec is passed to a delay block 87. This compensates for the delays introduced by the video coding process and thus ensures synchronisation of audio and video content.

The system control block 84 of the multimedia terminal controls end-to-network signalling using an appropriate control protocol (signalling block 88) to establish a common mode of operation between a transmitting and a receiving terminal. The signalling block 88 exchanges information about the encoding and decoding capabilities of the transmitting and receiving terminals and can be used to enable the various coding modes of the video encoder. The system control block 84 also controls the use of data encryption. Information regarding the type of encryption to be used in data transmission is passed from encryption block 89 to the multiplexer/de-multiplexer (MUX/DMUX unit) 90.

During data transmission from the multimedia terminal, the MUX/DMUX unit 90 combines encoded and synchronised video and audio streams with data input from the telematic equipment 83 and possible control data, to form a single bit-stream. Information concerning the type of data encryption (if any) to be applied to the bit-stream, provided by encryption block 89, is used to select an encryption mode. Correspondingly, when a multiplexed and possibly encrypted multimedia bit-stream is being received, MUX/DMUX unit 90 is responsible for decrypting the bit-stream, dividing it into its constituent multimedia components and passing those components to the appropriate codec(s) and/or terminal equipment for decoding and reproduction.

If the multimedia terminal 80 is a mobile terminal, that is, if it is equipped with a radio transceiver 93, it will be understood by those skilled in the art that it may also comprise additional elements. In one embodiment it comprises a user interface having a display and a keyboard, which enables operation of the multimedia terminal 80 by a user, a central processing unit, such as a microprocessor, which controls the blocks responsible for different functions of the multimedia terminal, a random access memory RAM, a read only memory ROM, and a digital camera. The microprocessor's operating instructions, that is program code corresponding to the basic functions of the multimedia terminal 80, is stored in the read-only memory ROM and can be executed as required by the microprocessor, for example under control of the user. In accordance with the program code, the microprocessor uses the radio transceiver 93 to form a connection with a mobile communication network, enabling the multimedia terminal 80 to transmit information to and receive information from the mobile communication network over a radio path.

The microprocessor monitors the state of the user interface and controls the digital camera. In response to a user command, the microprocessor instructs the camera to record digi-

tal images into the RAM. Once an image is captured, or alternatively during the capturing process, the microprocessor segments the image into image segments (for example macroblocks) and uses the encoder to perform motion compensated encoding of the segments in order to generate a compressed image sequence, as explained in the foregoing description. A user may command the multimedia terminal 80 to display the captured images on its display or to send the compressed image sequence using the radio transceiver 93 to another multimedia terminal, a video telephone connected to a fixed line network (PSTN) or some other telecommunications device. In a preferred embodiment, transmission of image data is started as soon as the first segment is encoded so that the recipient can start a corresponding decoding process with a minimum delay.

Although described in the context of particular embodiments, it will be apparent to those skilled in the art that a number of modifications and various changes to these teachings may be made. Thus, while the invention has been particularly shown and described with respect to one or more preferred embodiments thereof, it will be understood by those skilled in the art that certain modifications or changes may be made therein without departing from the scope and spirit of the invention as set forth above.

In particular, according to a second possible embodiment of the invention, a sequence QP is not transmitted but an application specific constant is used as sequence QP instead.

In a third possible embodiment of the invention the sequence QP can be updated depending on the changing characteristics of the video sequence if a reliable way of transmitting the new sequence QP is available. The updated SQP value can be either included in the encoded bit-stream representative of the video sequence or can be transmitted directly from encoder to decoder in an associated control channel.

In a fourth possible embodiment of the invention, if QP is constant for the whole video sequence only the value of the sequence QP is transmitted together with the information that it should be used as the QP for all the pictures/slices.

What is claimed is:

1. A method of encoding a digital video sequence for use in a video coding application to produce an encoded video bit-stream representative of the digital video sequence, the digital video sequence comprising a number of frames, each frame of said sequence comprising an array of pixels divided into a plurality of blocks, each block comprising a certain number of said pixels, said method comprising:

encoding a frame of the digital video sequence by applying motion compensated prediction to blocks of pixels for producing corresponding blocks of prediction error values;

applying a transform coding technique to said blocks of prediction error values to produce sets of transform coefficient values representative of said blocks of prediction error values;

defining a default level of quantization for use in encoding of the digital video sequence to quantize the sets of transform coefficient values; and

providing an indication of the default level of quantization to a decoding process.

2. An encoding method according to claim 1, wherein said indication of the default level of quantization is provided in the encoded bit-stream representative of the digital video sequence.

3. An encoding method according to claim 2, wherein the encoded bit-stream is transmitted from a video encoding device to a corresponding video decoding device.

4. An encoding method according to claim 1, wherein the default level of quantization is updated during the encoding of the digital video sequence, said method further comprising providing an indication of the updated default level of quantization to a decoding process.

5. An encoding method according to claim 1, wherein said sets of transform coefficient values are quantized to yield sets of quantized transform coefficient values representative of said blocks of prediction error values based on a level of quantization different from the default level of quantization.

6. An encoding method according to claim 5, further comprising providing to a decoding process an indication of a difference between said level of quantization and the default level of quantization.

7. An encoding method according to claim 5, wherein said level of quantization is adjusted from one frame of the digital video sequence to another such that an actual level of quantization applied to the sets of transform coefficients for a particular frame of the digital video sequence is different from the default level of quantization.

8. An encoding method according to claim 7, wherein said actual level of quantization is representable as a difference with respect to the default level of quantization.

9. An encoding method according to claim 7, further comprising providing to a decoding process an indication of a difference between said actual level of quantization and the default level of quantization.

10. An encoding method according to claim 5, wherein the plurality of blocks of pixels, into which a frame of said digital video sequence is divided, are grouped into one or more segments and wherein the level of quantization applied to said sets of transform coefficient values is adjusted from one segment of a frame to another such that an actual level of quantization applied to the sets of transform coefficients for a particular segment of a frame is different from the default level of quantization.

11. An encoding method according to claim 10, further comprising providing to a decoding process an indication of a difference between said level of quantization and the default level of quantization.

12. A video encoder for encoding a digital video sequence to produce an encoded video bit-stream representative of the digital video sequence, the digital video sequence comprising a number of frames, each frame of said sequence comprising an array of pixels divided into a plurality of blocks, each block comprising a certain number of said pixels, said video encoder comprising:

means for encoding a frame of the digital video sequence by applying motion compensated prediction to blocks of pixels to provide corresponding blocks of prediction error values;

means for transforming said blocks of prediction error values for providing sets of transform coefficient values representative of said blocks of prediction error values; means for selecting a default level of quantization for quantizing said sets of transform coefficient values; and

means for providing an indication of said default level of quantization in the encoded bit-stream representative of the digital video sequence.

13. A video encoder according to claim 12, wherein said sets of transform coefficient values are quantized to yield sets of quantized transform coefficient values representative of said blocks of prediction error values based on a level of quantization different from the default level of quantization.

27

14. A video encoder according to claim 13, arranged to provide an indication of a difference between said level of quantization and the default level of quantization in the encoded bit-stream.

15. A video encoder according to claim 12, wherein the default level of quantization can be updated and the video encoder is arranged to provide an indication of the updated default level of quantization in the encoded bit-stream.

16. A video encoder according to claim 15, wherein said sets of transform coefficient values are quantized to yield sets of quantized transform coefficient values representative of said blocks of prediction error values based on a level of quantization different from the updated default level of quantization.

17. A video encoder according to claim 12, provided in a multimedia terminal.

18. A video encoder according to claim 12, provided in a radio telecommunications device.

19. A video encoder according to claim 13, wherein said level of quantization applied to said sets of transform coefficient values can be adjusted from one frame of the digital video sequence to another so as to apply an actual level of quantization to the sets of transform coefficients for a particular frame of the digital video sequence and wherein said actual level of quantization is different from the default level of quantization.

20. A video encoder according to claim 19, arranged to provide an indication of said difference with respect to the default level of quantization in the encoded bit-stream representative of the digital video sequence.

21. A video encoder according to claim 13, arranged to group the plurality of blocks into which a frame of said digital video sequence is divided into one or more segments and to

28

adjust the level of quantization applied to said sets of transform coefficient values from one segment of a frame to another so as to apply an actual level of quantization to the sets of transform coefficients for a particular segment of a frame, wherein said actual level of quantization is different from the default level of quantization, said video encoder further arranged to represent the actual level of quantization for use in the particular segment as a difference with respect to the default level of quantization.

22. A video encoder according to claim 21, further arranged to provide an indication of said difference with respect to the default level of quantization in the encoded bit-stream representative of the digital video sequence.

23. A video encoder for encoding a digital video sequence to produce an encoded video bit-stream representative of the digital video sequence, the digital video sequence comprising a number of frames, each frame of said sequence comprising an array of pixels divided into a plurality of blocks, each block comprising a certain number of said pixels, said video encoder comprising:

a module for encoding a frame of the digital video sequence by applying motion compensated prediction to blocks of pixels to provide corresponding blocks of prediction error values;

a module for transforming said blocks of prediction error values for providing sets of transform coefficient values representative of said blocks of prediction error values; and

a module for selecting a default level of quantization for quantizing said sets of transform coefficient values, wherein the default level is specific to the video coding applications.

(57) **ABSTRACT**

A method and device for coding of digital video sequence, wherein an indication of quantization parameter (QP) is provided in the encoded bit-stream for decoding purposes. The QP related information is indicated by introducing a sequence level quantization parameter value SQP. More specifically, instead of coding the absolute values of picture/slice QPs, an indication of the difference ΔQP between the sequence level quantization parameter SQP and the picture/slice QP is provided. This eliminates the need to transmit a full QP for every picture/slice, and enables a statistically smaller difference value to be transmitted, thus providing a reduction in transmission bit-rate. The difference value is subsequently used in a corresponding decoder to reconstruct the picture/slice QP.

(57) **ABSTRACT**

A system and method for improving prediction error coding performance of various video compression algorithms. Various embodiments combine the energy compaction features of transform coding with localization properties of spatial coding. In various embodiments, the effects of pixel "outliers" are removed from the transform and are coded separately as a spatially coded pixel prediction, thereby improving the coding gain of the transform.

SPATIALLY ENHANCED TRANSFORM CODING

FIELD OF THE INVENTION

The present invention relates to the coding and decoding of digital video material. More particularly, the present invention relates to prediction error coding in both frequency and spatial domains.

BACKGROUND OF THE INVENTION

This section is intended to provide a background or context to the invention that is recited in the claims. The description herein may include concepts that could be pursued, but are not necessarily ones that have been previously conceived or pursued. Therefore, unless otherwise indicated herein, what is described in this section is not prior art to the description and claims in this application and is not admitted to be prior art by inclusion in this section.

A video codec comprises an encoder that transforms input video into a compressed representation suited for storage and/or transmission and a decoder that can uncompress the compressed video representation back into a viewable form. Typically, the encoder discards some information in the original video sequence in order to represent the video in a more compact form, i.e., at a lower bitrate.

Typical hybrid video codecs, for example ITU-T H.263 and H.264, encode video information in two phases. In the first phase, pixel values in a certain picture area or "block" are predicted. These pixel values can be predicted, for example, by motion compensation mechanisms, which involve finding and indicating an area in one of the previously coded video frames that corresponds closely to the block being coded. Additionally, pixel values can be predicted via by spatial mechanisms, which involve using the pixel values around the block to be coded in a specified manner. The second phase involves coding the prediction error, i.e. the difference between the predicted block of pixels and the original block of pixels. This is typically accomplished by transforming the difference in pixel values using a specified transform (e.g., a Discrete Cosine Transform (DCT) or a variant thereof), quantizing the coefficients, and entropy coding the quantized coefficients. By varying the fidelity of the quantization process, the encoder can control the balance between the accuracy of the pixel representation (i.e., the picture quality) and the size of the resulting coded video representation (i.e., the file size or transmission bitrate).

The decoder reconstructs output video by applying prediction mechanisms that are similar to those used by the encoder in order to form a predicted representation of the pixel blocks (using motion or spatial information created by the encoder and stored in the compressed representation) and prediction error decoding (the inverse operation of the prediction error coding, recovering the quantized prediction error signal in the spatial pixel domain). After applying prediction and prediction error decoding processes, the decoder sums up the prediction and prediction error signals (i.e., the pixel values) to form the output video frame. The decoder (and encoder) can also apply additional filtering processes in order to improve the quality of the output video before passing it for display and/or storing it as a prediction reference for the forthcoming frames in the video sequence.

In typical video codecs, the motion information is indicated with motion vectors associated with each motion-compensated image block. Each of these motion vectors represents the displacement of the image block in the picture to be

2

coded (in the encoder side) or decoded (in the decoder side) and the prediction source block in one of the previously coded or decoded pictures. In order to represent motion vectors efficiently, motion vectors are typically coded differentially with respect to block specific predicted motion vectors. In a typical video codec, the predicted motion vectors are created in a predefined way, for example by calculating the median of the encoded or decoded motion vectors of the adjacent blocks.

Typical video encoders utilize Lagrangian cost functions to find optimal coding modes, e.g., the desired macroblock mode and associated motion vectors. This kind of cost function uses a weighting factor λ to tie together the exact or estimated image distortion due to lossy coding methods and the exact or estimated amount of information that is required to represent the pixel values in an image area:

$$C = D + \lambda R \quad (1)$$

In Eq. (1), C is the Lagrangian cost to be minimized, D is the image distortion (e.g., the mean squared error) with the mode and motion vectors considered, and R the number of bits needed to represent the required data to reconstruct the image block in the decoder (including the amount of data to represent the candidate motion vectors).

Transform coding of the prediction error signal in video or image compression system typically comprises DCT-based linear transform, quantization of the transformed DCT coefficients, and context based entropy coding of the quantized coefficients. However, the transform can efficiently pack energy of the prediction error signal only under certain statistics, and the coding performance deteriorates when the prediction error to be transformed becomes less correlated. This causes suboptimal performance, especially in modern video and image coding systems employing advanced motion compensation and spatial prediction processes in order to achieve good quality predictions for the image blocks to be coded (thus, minimizing and decorrelating the prediction error signal).

To address some of the above issues, a number of hybrid video coding schemes have been developed. These hybrid systems typically comprise a hybrid of two redundancy reduction techniques—prediction and transformation. Prediction can take the form of inter-picture prediction, which is used to remove temporal redundancies in the signal. Intra-picture prediction may also be used in the H.264/Advanced Video Coding (AVC) standard where spatial redundancies are removed by exploiting the similarities between neighboring regions within a picture frame. As a consequence of these inter-picture and intra-picture prediction techniques, a residual/error signal is formed by removing the predicted picture frame from the original. This prediction error signal is then typically block transform coded using an 8x8 DCT transform in order to reduce spatial redundancies in the signal.

SUMMARY OF THE INVENTION

Various embodiments of the present invention provide a system and method for representing the prediction error signal as a weighted sum of different basis functions of a selected transform and quantized spatial samples. The basis functions of the selected transform may comprise an orthogonal set of basis vectors, or the basis functions may not comprise an orthogonal set. According to various embodiments, the prediction error signal for a single image block is constructed using both transform basis functions and spatial samples (i.e., pixel values), thereby combining the desired features of both

3

the transform and spatial coding approaches discussed previously. This allows for the utilization of those selected transform basis functions that give good overall representation of the image block with minimal amount of transform coefficients (representing the component of prediction error signal that is well correlated with the basis functions). Additionally, various embodiments of the present invention allow for the efficient spatial representation of those components of the prediction error signal of the same image block that are not well correlated with the basis functions of the applied transform (such as certain types of sensor noise, high frequency texture and edge information).

According to various embodiments of the present invention, a system and method of encoding a prediction error signal for a block of data comprises calculating a difference signal representing differences between sample values of a predicted block of data and values for an original input block. Transform coding and spatial coding are both performed to the difference signal, thereby creating a first and second representations of first and second components of the difference signal. The first and second representations are then combined to provide the prediction error signal.

Various embodiments of the present invention also provide a system and method of decoding a prediction error signal for a block of data, comprising receiving a coded prediction error signal, the coded prediction error signal including a plurality of transform coefficients and a plurality of spatial samples. The plurality of transformed coefficients are decoded into decoded transform information, and the plurality of spatial samples are decoded into decoded spatial information. The decoded transform information, the decoded spatial information, and a reconstructed prediction of the block of data are then added, thereby forming a decoded representation of the block of data.

The implementations of various embodiments of the present invention serve to improve the compression efficiency of modern video and image codecs. Although a certain amount of increased computational complexity of encoding may be needed, fast algorithms can be applied in order to lower the encoding complexity that approaches the complexity level for traditional transform based coding. Any effect on the complexity for a decoder is negligible when implementing various embodiments of the present invention.

These and other advantages and features of the invention, together with the organization and manner of operation thereof, will become apparent from the following detailed description when taken in conjunction with the accompanying drawings, wherein like elements have like numerals throughout the several drawings described below.

BRIEF DESCRIPTION OF THE DRAWINGS

DETAILED DESCRIPTION OF VARIOUS EMBODIMENTS

Various embodiments of the present invention provide a system and method for representing the prediction error signal as a weighted sum of different basis functions of a selected transform and quantized spatial samples. According to various embodiments, the prediction error signal for a single image block is constructed using both transform basis functions and spatial samples (i.e., pixel values), thereby combining the desired features of both the transform and spatial coding approaches discussed previously. This allows for the utilization of those selected transform basis functions that give good overall representation of the image block with minimal amount of transform coefficients (representing the component of prediction error signal that is well correlated with the basis functions). Additionally, various embodiments of the present invention allow for the efficient spatial representation of those components of the prediction error signal of the same image block that are not well correlated with the basis functions of the applied transform (such as certain types of sensor noise, high frequency texture and edge information).

FIGS. 1 and 2 show a simplified example of how various embodiments of the present invention are operable in one dimension. FIG. 1 shows an example of basis functions of a one-dimensional linear transform that can be used to encode image data (namely a Hadamard transform). The weighted sum of these four basis functions can be used to represent any four samples. FIG. 2(a) is an example of four scalar values that are to be coded or decoded and representing the prediction error signal between the original image and the prediction image. In FIG. 2(b), the four weighted basis functions from FIG. 1 are summed to the prediction error signal (1.5 times the first, 0.5 times the second, -0.5 times the third and -0.5 times the fourth basis function). In FIG. 2(c) it is demonstrated how the same prediction error signal can be reconstructed by summing up only the first basis function and a single spatial sample represented by an arrow. In this example, compression efficiency improvement can be expected, as the signal is represented by a single transform coefficient and a single spatial sample instead of four transform coefficients weighting the four Hadamard basis functions (as shown in FIG. 2(b)).

FIG. 3 is a block diagram of a video encoder constructed in accordance with one embodiment of the present invention. More particularly, FIG. 3 shows how an image to be encoded 300 undergoes pixel prediction 302, prediction error coding 303 and prediction error decoding 304. For pixel prediction 302, the image 300 undergoes both inter-prediction 306 and intra-prediction 308 which, after mode selection 310, results in prediction representation of an image block 312. A preliminary reconstructed image 314 is also used for intra-pre-

5

diction 308. Once all of the image blocks are processed, the preliminary reconstructed image 314 undergoes filtering at 316 to create a final reconstructed image 340, which is sent to a reference frame memory 318 and is also used for inter-prediction 306 of future frames.

The prediction representation of the image block 312, as well as the image to be encoded 300, are used together to define a prediction error signal 320 which is used for prediction error coding 303. In prediction error coding 303, the prediction error signal 320 undergoes feature selection 322 and spatial quantization 324, as well as transform 326 and quantization 328 (both after feature selection 322). The data describing prediction error and predicted representation of the image block 312 (e.g., motion vectors, mode information and quantized DCT+spatial samples) are passed to entropy coding 330. The prediction error decoding 304 is substantially the opposite of the prediction error coding 303, with the prediction error decoding including an inverse spatial quantizer 332, an inverse transform 334 and an inverse quantization 336. The result of the prediction error decoding 304 is a reconstructed prediction error signal 338, which is used in combination with the predicted representation of the image block 312 to create the preliminary reconstructed image 314.

FIG. 4 is a flow chart showing one encoder algorithm which may be used in an embodiment of the present invention. However, as discussed below, a variety of different algorithms may be used according to principles of the present invention. At 400 in FIG. 4, the difference between sample values of a predicted block and an original input block is calculated. It should be noted that "values" and "outlier values" as used herein are intended to refer to these difference values. At 410, outlier values are found. In this case, the amplitude depends on the expected accuracy of the coded representation; smaller amplitude representations qualify as outliers if one is targeting high bitrate good quality representation, and only high amplitude representations qualify if one is targeting a lower bitrate, lower quality representation. At 420, the modified prediction error signal is transform coded (involving transform, quantization and entropy coding), with the outlier values being substituted by interpolated representations of those values, e.g., by averaging the neighboring prediction error values. At 430, the modified prediction error signals are transform decoded back to the spatial domain. At 440, spatial coding is applied (involving quantization and entropy coding without transform) to the difference between the original outlier values and the transform decoded outlier values. At 450, the final coded representation of the prediction error signal is formed by joining the transform coded data and the spatial coded data. In an alternative embodiment, the spatial coding occurs before transform coding.

When considering the one-dimensional example depicted in FIGS. 2(a)-2(c), the algorithm outlined in FIG. 4 would process the relevant data as follows. As discussed previously, FIG. 2(a) represents the difference signal [1 1 3 1] to be coded. In this case, [3] is an outlier. Therefore, the prediction error signal is modified by substituting the [3] with an average of the second and fourth samples, making the signal [1 1 1 1]. The difference between the original outlier sample ([3]) and the transform coded outlier value ([1]) is then spatial coded, making the spatial coded signal [0 0 2 0]. The entropy coded representations of the transform coded and spatial coded signals are then written to the bitstream. Thereafter, the decoder can recover the coded signal by adding up the inverse transformed data [1 1 1 1] and the inverse spatial coded data [0 0 2 0] (together with the prediction samples of the image block).

When considering the above example, it is important to note that the choice of Hadamard basis vectors for the trans-

6

form is only intended to be exemplary in nature. In fact, the various methods and techniques described herein can be applied to any transform employing basis functions, and the basis functions do not necessarily need to be orthogonal.

A video or image codec, according to various embodiments the present invention, can be implemented in various ways. In the case of an encoder, the encoder can use different strategies to find the desired transform coefficients and spatial samples. For example, an encoder can first transform code the signal and apply spatial coding to the residual. The encoder can also first apply spatial coding to the signal, followed by transform coding of the residual. Additionally, some or all of the transform coefficients can be set to zero in order to improve the coding performance. Some or all spatial samples can also be set to zero in order to improve the coding performance. An encoder can also iteratively modify transform coefficients and/or spatial samples in order to improve the coding performance until a desired performance or a maximum defined number of iterations is achieved.

In terms of quantization and dequantization, the quantization and dequantization of transform coefficients and spatial samples can be tied together (e.g., a quantization step size for both transform coefficients and spatial samples can be derived from a single parameter). Alternatively, different quantizations and dequantizations can be applied to transform coefficients and spatial samples.

For the coding and decoding of spatial samples, such coding and decoding can depend on transform coefficients and vice versa. Alternatively, the coding and decoding of spatial samples, transform coefficients or both can depend on the prediction signal, on the other transform coefficients and spatial samples in the same image or in other images.

In addition to the above, it can be indicated that there are no transform coefficients or spatial samples for a specific image area or image. It can also be indicated that only spatial coding or only transform coding is used for a specific image area or image. The number of spatial samples can be coded and decoded as one unit, for example representing certain patterns of textures. Pre- and/or post-processing mechanisms can be applied to the prediction signal, prediction error signal reconstructed signal or any combination thereof. The method can be used to code and decode other information instead or in addition to the prediction error signals. The codec can limit the usage of either transform coefficients (e.g., allow only low frequency transform coefficients to be present in the coded representation of the signal) or spatial samples.

FIG. 5 shows a decoding process according to various embodiments of the present invention. At 500 in FIG. 5, a video decoder receives a coded prediction error signal which comprises both transformed coefficients and spatial samples. At 510, both the transformed coefficients and the spatial samples are decoded. At 520, the decoded transform information, the decoded spatial information and reconstructed prediction of the image block are added together to form decoded representation of the image block.

FIG. 6 is a block diagram of a video decoder constructed in accordance with one embodiment of the present invention. As shown in FIG. 6, entropy decoding 600 is followed by both prediction error decoding 602 and pixel prediction 604. In prediction error decoding 602, in addition to an inverse transform 606 and inverse quantization 608, an inverse spatial quantizer 610 is used as discussed herein, ultimately resulting in a reconstructed prediction error signal 612. For pixel prediction 604, either intra-prediction or inter-prediction occurs at 614 to create a predicted representation of an image block 616. The predicted representation of the image block 616 is used in conjunction with the reconstructed prediction error

7

signal **612** to create a preliminary reconstructed image **618**, which in turn can be used both for prediction **614**. Once all of the image blocks have been processed, the preliminary reconstructed image **618** is passed for filtering **620**. The filtered image can also be stored in reference frame memory **624**, making it usable for prediction **614** as well.

FIG. 7 shows a system **10** in which various embodiments of the present invention can be utilized, comprising multiple communication devices that can communicate through one or more networks. The system **10** may comprise any combination of wired or wireless networks including, but not limited to, a mobile telephone network, a wireless Local Area Network (LAN), a Bluetooth personal area network, an Ethernet LAN, a token ring LAN, a wide area network, the Internet, etc. The system **10** may include both wired and wireless communication devices.

For exemplification, the system **10** shown in FIG. 7 includes a mobile telephone network **11** and the Internet **28**. Connectivity to the Internet **28** may include, but is not limited to, long range wireless connections, short range wireless connections, and various wired connections including, but not limited to, telephone lines, cable lines, power lines, and the like.

The exemplary communication devices of the system **10** may include, but are not limited to, an electronic device **50**, a combination personal digital assistant (PDA) **14** and mobile telephone **14**, a PDA **16**, an integrated messaging device (IMD) **18**, a desktop computer **20**, a notebook computer **22**, etc. The communication devices may be stationary or mobile as when carried by an individual who is moving. The communication devices may also be located in a mode of transportation including, but not limited to, an automobile, a truck, a taxi, a bus, a train, a boat, an airplane, a bicycle, a motorcycle, etc. Some or all of the communication devices may send and receive calls and messages and communicate with service providers through a wireless connection **25** to a base station **24**. The base station **24** may be connected to a network server **26** that allows communication between the mobile telephone network **11** and the Internet **28**. The system **10** may include additional communication devices and communication devices of different types.

The communication devices may communicate using various transmission technologies including, but not limited to, Code Division Multiple Access (CDMA), Global System for Mobile Communications (GSM), Universal Mobile Telecommunications System (UMTS), Time Division Multiple Access (TDMA), Frequency Division Multiple Access (FDMA), Transmission Control Protocol/Internet Protocol (TCP/IP), Short Messaging Service (SMS), Multimedia Messaging Service (MMS), e-mail, Instant Messaging Service (IMS), Bluetooth, IEEE 802.11, etc. A communication device involved in implementing various embodiments of the present invention may communicate using various media including, but not limited to, radio, infrared, laser, cable connection, and the like.

FIGS. 8 and 9 show one representative electronic device **50** within which the present invention may be implemented. It should be understood, however, that the present invention is not intended to be limited to one particular type of device. The electronic device **50** of FIGS. 8 and 9 includes a housing **30**, a display **32** in the form of a liquid crystal display, a keypad **34**, a microphone **36**, an ear-piece **38**, a battery **40**, an infrared port **42**, an antenna **44**, a smart card **46** in the form of a UICC according to one embodiment of the invention, a card reader **48**, radio interface circuitry **52**, codec circuitry **54**, a control-

8

ler **56** and a memory **58**. Individual circuits and elements are all of a type well known in the art, for example in the Nokia range of mobile telephones.

The various embodiments of the present invention described herein is described in the general context of method steps or processes, which may be implemented in one embodiment by a computer program product, embodied in a computer-readable medium, including computer-executable instructions, such as program code, executed by computers in networked environments. Generally, program modules may include routines, programs, objects, components, data structures, etc. that perform particular tasks or implement particular abstract data types. Computer-executable instructions, associated data structures, and program modules represent examples of program code for executing steps of the methods disclosed herein. The particular sequence of such executable instructions or associated data structures represents examples of corresponding acts for implementing the functions described in such steps or processes.

Software and web implementations of various embodiments of the present invention can be accomplished with standard programming techniques with rule-based logic and other logic to accomplish various database searching steps or processes, correlation steps or processes, comparison steps or processes and decision steps or processes. It should be noted that the words "component" and "module," as used herein and in the following claims, is intended to encompass implementations using one or more lines of software code, and/or hardware implementations, and/or equipment for receiving manual inputs.

The foregoing description of embodiments of the present invention have been presented for purposes of illustration and description. The foregoing description is not intended to be exhaustive or to limit embodiments of the present invention to the precise form disclosed, and modifications and variations are possible in light of the above teachings or may be acquired from practice of various embodiments of the present invention. The embodiments discussed herein were chosen and described in order to explain the principles and the nature of various embodiments of the present invention and its practical application to enable one skilled in the art to utilize the present invention in various embodiments and with various modifications as are suited to the particular use contemplated.

What is claimed is:

1. A method, comprising:

calculating, by a processor, a difference signal representing differences between sample values of a predicted block of data and values for an original input block;

performing, by a processor, transform coding to the difference signal, thereby creating a first representation of a first component of the difference signal;

performing, by a processor, spatial coding to the difference signal, thereby creating a second representation of a first component of the difference signal;

joining, by a processor, the first and second representations to form a coded prediction error signal; and
at least one of transmitting or storing the coded prediction error signal.

2. The method of claim 1, further comprising, before performing transform coding and spatial coding, substituting outlier values in the difference signal with non-outlier values to create a modified prediction error signal.

3. The method of claim 2, wherein transform coding is applied to the modified prediction error signal and spatial coding is applied to a residual thereof.

9

4. The method of claim 2, wherein spatial coding is applied to the modified prediction error signal and transform coding is applied to a residual thereof.

5. The method of claim 1, wherein, for transform coding, at least one transform coefficient is set to zero.

6. The method of claim 1, wherein, for spatial coding, at least one spatial sample is set to zero.

7. The method of claim 2, wherein the non-outlier values used to replace the outlier values comprise an average of neighboring prediction error values.

8. The method of claim 1, further comprising providing an indication that no transform coefficients exist in the block of data if appropriate.

9. The method of claim 1, further comprising providing an indication that no spatial samples exist in the block of data if appropriate.

10. The method of claim 1, wherein for the transform coding, a transform coefficient is formed, the transform coefficient comprising a weighting coefficient of a discrete transform basis vector.

11. The method of claim 10, wherein the discrete transform comprises a discrete orthogonal transform.

12. A computer program product, embodied in a non-transitory computer-readable medium, comprising computer code configured to perform the method of claim 1.

13. An apparatus, comprising:

a processor; and

a memory unit communicatively connected to a controller and comprising:

computer code for performing transform coding to the difference signal, thereby creating a first representation of a first component of the difference signal;

computer code for performing spatial coding to the difference signal, thereby creating a second representation of a first component of the difference signal; and
computer code for joining the first and second representations.

14. The apparatus of claim 13, wherein the memory unit further comprises computer code for, before performing transform coding and spatial coding, substituting outlier values in the difference signal with non-outlier values to create a modified prediction error signal.

15. The apparatus of claim 14, wherein transform coding is applied to the modified prediction error signal and spatial coding is applied to a residual thereof.

16. The apparatus of claim 14, wherein spatial coding is applied to the modified prediction error signal and transform coding is applied to a residual thereof.

17. The apparatus of claim 13, wherein, for transform coding, at least one transform coefficient is set to zero.

18. The apparatus of claim 13, wherein, for spatial coding, at least one spatial sample is set to zero.

19. The apparatus of claim 13, wherein the non-outlier values used to replace the outlier values comprise an average of neighboring prediction error values.

20. The apparatus of claim 13, further comprising providing an indication that no transform coefficients exist in the block of data if appropriate.

21. The apparatus of claim 13, further comprising providing an indication that no spatial samples exist in the block of data if appropriate.

22. A method, comprising:

receiving a coded prediction error signal, the coded prediction error signal including a plurality of transform coefficients and a plurality of spatial samples;

decoding, by a processor, the plurality of transformed coefficients into decoded transform information;

10

decoding, by a processor, the plurality of spatial samples into decoded spatial information; and

adding, by a processor, the decoded transform information, the decoded spatial information, and a reconstructed prediction of the block of data, thereby forming a decoded representation of the block of data.

23. The method of claim 22, wherein an indication is provided that no transform coefficients exist in the block of data if appropriate.

24. The method of claim 22, wherein an indication is provided that no spatial samples exist in the block of data if appropriate.

25. The method of claim 22, wherein the decoding of the plurality of transformed coefficients and spatial samples includes dequantization of each, and wherein the dequantization of transformed coefficients and spatial samples are related to each other.

26. The method of claim 22, wherein the decoding of the plurality of transformed coefficients and spatial samples includes dequantization of each, and wherein the dequantization of transformed coefficients and spatial samples are different from each other.

27. The method of claim 22, wherein the decoding of the spatial samples is dependent upon the decoding of the transformed coefficients.

28. The method of claim 22, wherein the decoding of the transformed coefficients is dependent upon the decoding of the spatial samples.

29. The method of claim 22, wherein at least some of the plurality of spatial samples are decoded as a single unit.

30. A computer program product, embodied in a non-transitory computer-readable medium, comprising computer code configured to perform the method of claim 22.

31. An apparatus, comprising:

a processor; and

a memory unit communicatively connected to the processor and including:

computer code for processing a received coded prediction error signal, the coded prediction error signal including a plurality of transformed coefficients and a plurality of spatial samples;

computer code for decoding the plurality of transformed coefficients into decoded transform information;

computer code for decoding the plurality of spatial samples into decoded spatial information; and

computer code for adding the decoded transform information, the decoded spatial information, and a reconstructed prediction of the block of data, thereby forming a decoded representation of the block of data.

32. The apparatus of claim 31, wherein an indication is provided that no transform coefficients exist in the block of data if appropriate.

33. The apparatus of claim 31, wherein an indication is provided that no spatial samples exist in the block of data if appropriate.

34. The apparatus of claim 31, wherein the decoding of the plurality of transformed coefficients and spatial samples includes dequantization of each, and wherein the dequantization of transformed coefficients and spatial samples are related to each other.

35. The apparatus of claim 31, wherein the decoding of the plurality of transformed coefficients and spatial samples includes dequantization of each, and wherein the dequantization of transformed coefficients and spatial samples are different from each other.

11

36. The apparatus of claim 31, wherein the decoding of the spatial samples is dependent upon the decoding of the transformed coefficients.

37. The apparatus of claim 31, wherein the decoding of the transformed coefficients is dependent upon the decoding of the spatial samples. 5

38. The apparatus of claim 31, wherein at least some of the plurality of spatial samples are decoded as a single unit.

39. A method, comprising: 10

calculating, by a processor, a difference signal representing differences between sample values of a predicted block of data and values for an original input block;

substituting, by a processor, outlier values in the difference signal with non-outlier values to create a modified prediction error signal; 15

12

performing, by a processor, one of transform coding and spatial coding to the modified prediction error signal, creating one of a transform coded data and spatial coded data

performing, by a processor, an inverse of the one of transform coding and spatial coding;

applying, by a processor, the other of transform coding and spatial coding to a residual from the inverse transform or spatial decoding, creating the other of transform coded data and spatial coded data;

joining, by a processor, the transform coded data and the spatial coded data to form a coded prediction error signal; and

at least one of transmitting or storing the coded prediction error signal.

METHOD FOR CODING AND AN APPARATUS

TECHNICAL FIELD

There is provided a method for encoding, a method for decoding, an apparatus, computer program products, an encoder and a decoder.

BACKGROUND INFORMATION

This section is intended to provide a background or context to the invention that is recited in the claims. The description herein may include concepts that could be pursued, but are not necessarily ones that have been previously conceived or pursued. Therefore, unless otherwise indicated herein, what is described in this section is not prior art to the description and claims in this application and is not admitted to be prior art by inclusion in this section

A video codec may comprise an encoder which transforms input video into a compressed representation suitable for storage and/or transmission and a decoder that can uncompress the compressed video representation back into a viewable form, or either one of them. The encoder may discard some information in the original video sequence in order to represent the video in a more compact form, for example at a lower bit rate.

Many hybrid video codecs, operating for example according to the International Telecommunication Union's ITU-T H.263 and H.264 coding standards, encode video information in two phases. In the first phase, pixel values in a certain picture area or "block" are predicted. These pixel values can be predicted, for example, by motion compensation mechanisms, which involve finding and indicating an area in one of the previously encoded video frames (or a later coded video frame) that corresponds closely to the block being coded. Additionally, pixel values can be predicted by spatial mechanisms which involve finding and indicating a spatial region relationship, for example by using pixel values around the block to be coded in a specified manner.

Prediction approaches using image information from a previous (or a later) image can also be called as Inter prediction methods, and prediction approaches using image information within the same image can also be called as Intra prediction methods.

The second phase is one of coding the error between the predicted block of pixels and the original block of pixels. This may be accomplished by transforming the difference in pixel values using a specified transform. This transform may be e.g. a Discrete Cosine Transform (DCT) or a variant thereof. After transforming the difference, the transformed difference may be quantized and entropy encoded.

By varying the fidelity of the quantization process, the encoder can control the balance between the accuracy of the pixel representation, (in other words, the quality of the picture) and the size of the resulting encoded video representation (in other words, the file size or transmission bit rate).

The decoder reconstructs the output video by applying a prediction mechanism similar to that used by the encoder in order to form a predicted representation of the pixel blocks (using the motion or spatial information created by the encoder and stored in the compressed representation of the image) and prediction error decoding (the inverse operation of the prediction error coding to recover the quantized prediction error signal in the spatial domain).

After applying pixel prediction and error decoding processes the decoder combines the prediction and the prediction error signals (the pixel values) to form the output video frame.

The decoder (and encoder) may also apply additional filtering processes in order to improve the quality of the output video before passing it for display and/or storing as a prediction reference for the forthcoming frames in the video sequence.

In some video codecs, such as High Efficiency Video Coding Working Draft 4, video pictures may be divided into coding units (CU) covering the area of a picture. A coding unit consists of one or more prediction units (PU) defining the prediction process for the samples within the coding unit and one or more transform units (TU) defining the prediction error coding process for the samples in the coding unit. A coding unit may consist of a square block of samples with a size selectable from a predefined set of possible coding unit sizes. A coding unit with the maximum allowed size can be named as a largest coding unit (LCU) and the video picture may be divided into non-overlapping largest coding units. A largest coding unit can further be split into a combination of smaller coding units, e.g. by recursively splitting the largest coding unit and resultant coding units. Each resulting coding unit may have at least one prediction unit and at least one transform unit associated with it. Each prediction unit and transform unit can further be split into smaller prediction units and transform units in order to increase granularity of the prediction and prediction error coding processes, respectively. Each prediction unit may have prediction information associated with it defining what kind of a prediction is to be applied for the pixels within that prediction unit (e.g. motion vector information for inter predicted prediction units and intra prediction directionality information for intra predicted prediction units). Similarly, each transform unit may be associated with information describing the prediction error decoding process for samples within the transform unit (including e.g. discrete cosine transform (DCT) coefficient information). It may be signalled at coding unit level whether prediction error coding is applied or not for each coding unit. In the case there is no prediction error residual associated with the coding unit, it can be considered there are no transform units for the coding unit. The division of the image into coding units, and division of coding units into prediction units and transform units may be signalled in the bitstream allowing the decoder to reproduce the intended structure of these units.

In some video codecs, motion information is indicated by motion vectors associated with each motion compensated image block. These motion vectors represent the displacement of the image block in the picture to be coded (in the encoder) or decoded (at the decoder) and the prediction source block in one of the previously coded or decoded images (or pictures). In order to represent motion vectors efficiently, motion vectors may be coded differentially with respect to block specific predicted motion vector. In some video codecs, the predicted motion vectors are created in a predefined way, for example by calculating the median of the encoded or decoded motion vectors of the adjacent blocks.

Another way to create motion vector predictions is to generate a list or a set of candidate predictions from blocks in the current frame and/or co-located or other blocks in temporal reference pictures and signalling the chosen candidate as the motion vector prediction. A spatial motion vector prediction is a prediction obtained only on the basis of information of one or more blocks of the same frame than

the current frame whereas temporal motion vector prediction is a prediction obtained on the basis of information of one or more blocks of a frame different from the current frame. It may also be possible to obtain motion vector predictions by combining both spatial and temporal prediction information of one or more encoded blocks. These kinds of motion vector predictions are called as spatio-temporal motion vector predictions.

In addition to predicting the motion vector values, the reference index in the reference picture list can be predicted. The reference index may be predicted from blocks in the current frame and/or co-located or other blocks in a temporal reference picture. Moreover, some high efficiency video codecs employ an additional motion information coding/decoding mechanism, often called merging/merge mode, where all the motion field information, which includes motion vector and corresponding reference picture index for each available reference picture list, may be predicted and used without any modification or correction. Similarly, predicting the motion field information may be carried out using the motion field information of blocks in the current frame and/or co-located or other blocks in temporal reference pictures and the used motion field information is signalled among a list of motion field candidate list filled with motion field information of available blocks in the current frame and/or co-located or other blocks in temporal reference pictures.

In some video codecs the prediction residual after motion compensation is first transformed with a transform kernel (like DCT) and then coded. The reason for this is that often there still exists some correlation among the residual and transform can in many cases help reduce this correlation and provide more efficient coding.

Some video encoders utilize Lagrangian cost functions to find optimal coding modes, e.g. the desired Macroblock mode and associated motion vectors. This kind of cost function uses a weighting factor λ to tie together the (exact or estimated) image distortion due to lossy coding methods and the (exact or estimated) amount of information that is required to represent the pixel values in an image area:

$$C=D+\lambda R \quad (1)$$

where C is the Lagrangian cost to be minimized, D is the image distortion (e.g. Mean Squared Error) with the mode and motion vectors considered, and R the number of bits needed to represent the required data to reconstruct the image block in the decoder (including the amount of data to represent the candidate motion vectors).

Some video codecs such as hybrid video codecs may generate a list of motion vector predictions (MVP) consisting of motion vectors of spatial adjacent blocks (spatial MVP) and/or motion vectors of blocks in a previously decoded frame (temporal MVP). One of the candidate motion vectors in the list is signalled to be used as the motion vector prediction of the current block. After the list is generated, some of the motion vector prediction candidates may have the same motion information. In this case, the identical motion vector prediction candidates may be removed to reduce redundancy. During the decoding, if the temporal motion vector prediction information is unavailable due to e.g. loss of reference frame, the decoder may not know if the temporal motion vector prediction candidate in the list is to be removed. This may lead to uncertainty for mapping the decoded candidate index to the candidates whose removal decision is based on comparing motion information with the temporal motion vector prediction. As a result, false assignment of motion vector prediction can-

didates may occur which may lead to degradation in the picture quality and drift of false motion information throughout the decoding process.

SUMMARY

The present invention introduces a method for generating a motion vector prediction list for an image block. In some embodiments video codecs employ in a motion prediction candidate list construction a way to reduce the complexity of the implementation. This can be achieved by performing a limited number of motion information comparisons between candidate pairs to remove the redundant candidates rather than comparing every available candidate pair. The decision of whether comparing two candidates may depend on the order of the candidates to be considered for the list and/or coding/prediction mode and/or location of the blocks associated with the candidates. In some embodiments a video codec employs a merge process for motion information coding and creates a list of motion prediction candidates from which one of the candidates is to be signalled as the motion information for the current coding or prediction unit. The motion prediction candidates may consist of several spatial motion predictions and a temporal motion prediction. The spatial candidates are obtained from the motion information of e.g. spatial neighbour blocks.

According to a first aspect of the present invention there is provided a method comprising:

receiving a block of pixels including a prediction unit; determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

According to a second aspect of the present invention there is provided a method comprising:

receiving an encoded block of pixels including a prediction unit;

determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of

5

another spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

According to a third aspect of the present invention there is provided an apparatus comprising a processor and a memory including computer program code, the memory and the computer program code configured to, with the processor, cause the apparatus to:

receive a block of pixels

including a prediction unit;

determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

if at least one the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

According to a fourth aspect of the present invention there is provided an apparatus comprising a processor and a memory including computer program code, the memory and the computer program code configured to, with the processor, cause the apparatus to:

receive an encoded block of pixels

including a prediction unit;

determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of another spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

According to a fifth aspect of the present invention there is provided a storage medium having stored thereon a computer executable program code for use by an encoder, said program code comprises instructions for:

6

receiving a block of pixels including a prediction unit;

determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

select a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determine a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

compare motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

exclude the first spatial motion vector prediction candidate from the merge list, if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other

According to a sixth aspect of the present invention there is provided a storage medium having stored thereon a computer executable program code for use by a decoder, said program code comprises instructions for:

receiving an encoded block of pixels including a prediction unit;

determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

According to a seventh aspect of the present invention there is provided an apparatus comprising:

means for receiving a block of pixels including a prediction unit;

means for determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

7

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

According to an eighth aspect of the present invention there is provided an apparatus comprising:

means for receiving an encoded block of pixels including a prediction unit;

means for determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

means for selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

means for determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

means for comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

means for excluding the first spatial motion vector prediction candidate from the merge list, if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other.

DESCRIPTION OF THE DRAWINGS

For better understanding of the present invention, reference will now be made by way of example to the accompanying drawings in which:

FIG. 1 shows schematically an electronic device employing some embodiments of the invention;

FIG. 2 shows schematically a user equipment suitable for employing some embodiments of the invention;

FIG. 3 further shows schematically electronic devices employing embodiments of the invention connected using wireless and wired network connections;

FIG. 4a shows schematically an embodiment of the invention as incorporated within an encoder;

FIG. 4b shows schematically an embodiment of a prediction reference list generation and modification according to some embodiments of the invention;

FIGS. 5a and 5b show a flow diagram showing the operation of an embodiment of the invention with respect to the encoder as shown in FIG. 4a;

FIG. 6a illustrates an example of spatial and temporal prediction of a prediction unit;

FIG. 6b illustrates another example of spatial and temporal prediction of a prediction unit;

FIG. 7 shows schematically an embodiment of the invention as incorporated within a decoder;

FIGS. 8a and 8b show a flow diagram of showing the operation of an embodiment of the invention with respect to the decoder shown in FIG. 7;

FIG. 9 illustrates an example of a coding unit and some neighbour blocks of the coding unit;

FIG. 10a illustrates an example of a horizontal division of the coding unit;

FIG. 10b illustrates an example of a vertical division of the coding unit;

8

FIG. 11a illustrates locations of five spatial neighbours A0, A1, B0, B1, B2 for a prediction unit generated as the second prediction unit of a horizontally divided coding unit;

FIG. 11b illustrates locations of five spatial neighbours for a prediction unit generated as the second prediction unit of a vertically divided coding unit; and

FIG. 12 illustrates an example of blocks between some spatial neighbours of a coding unit.

DETAILED DESCRIPTION OF SOME EXAMPLE EMBODIMENTS

The following describes in further detail suitable apparatus and possible mechanisms for the provision of improving the prediction accuracy and hence possibly reducing information to be transmitted in video coding systems. In this regard reference is first made to FIG. 1 which shows a schematic block diagram of an exemplary apparatus or electronic device 50, which may incorporate a codec according to an embodiment of the invention.

The electronic device 50 may for example be a mobile terminal or user equipment of a wireless communication system. However, it would be appreciated that embodiments of the invention may be implemented within any electronic device or apparatus which may require encoding and decoding or encoding or decoding video images.

The apparatus 50 may comprise a housing 30 for incorporating and protecting the device. The apparatus 50 further may comprise a display 32 in the form of a liquid crystal display. In other embodiments of the invention the display may be any suitable display technology suitable to display an image or video. The apparatus 50 may further comprise a keypad 34. In other embodiments of the invention any suitable data or user interface mechanism may be employed. For example the user interface may be implemented as a virtual keyboard or data entry system as part of a touch-sensitive display. The apparatus may comprise a microphone 36 or any suitable audio input which may be a digital or analogue signal input. The apparatus 50 may further comprise an audio output device which in embodiments of the invention may be any one of: an earpiece 38, speaker, or an analogue audio or digital audio output connection. The apparatus 50 may also comprise a battery 40 (or in other embodiments of the invention the device may be powered by any suitable mobile energy device such as solar cell, fuel cell or clockwork generator). The apparatus may further comprise an infrared port 42 for short range line of sight communication to other devices. In other embodiments the apparatus 50 may further comprise any suitable short range communication solution such as for example a Bluetooth wireless connection or a USB/firewire wired connection.

The apparatus 50 may comprise a controller 56 or processor for controlling the apparatus 50. The controller 56 may be connected to memory 58 which in embodiments of the invention may store both data in the form of image and audio data and/or may also store instructions for implementation on the controller 56. The controller 56 may further be connected to codec circuitry 54 suitable for carrying out coding and decoding of audio and/or video data or assisting in coding and decoding carried out by the controller 56.

The apparatus 50 may further comprise a card reader 48 and a smart card 46, for example a UICC and UICC reader for providing user information and being suitable for providing authentication information for authentication and authorization of the user at a network.

The apparatus 50 may comprise radio interface circuitry 52 connected to the controller and suitable for generating

wireless communication signals for example for communication with a cellular communications network, a wireless communications system or a wireless local area network. The apparatus 50 may further comprise an antenna 44 connected to the radio interface circuitry 52 for transmitting radio frequency signals generated at the radio interface circuitry 52 to other apparatus(es) and for receiving radio frequency signals from other apparatus(es).

In some embodiments of the invention, the apparatus 50 comprises a camera capable of recording or detecting individual frames which are then passed to the codec 54 or controller for processing. In some embodiments of the invention, the apparatus may receive the video image data for processing from another device prior to transmission and/or storage. In some embodiments of the invention, the apparatus 50 may receive either wirelessly or by a wired connection the image for coding/decoding.

With respect to FIG. 3, an example of a system within which embodiments of the present invention can be utilized is shown. The system 10 comprises multiple communication devices which can communicate through one or more networks. The system 10 may comprise any combination of wired or wireless networks including, but not limited to a wireless cellular telephone network (such as a GSM, UMTS, CDMA network etc), a wireless local area network (WLAN) such as defined by any of the IEEE 802.x standards, a Bluetooth personal area network, an Ethernet local area network, a token ring local area network, a wide area network, and the Internet.

The system 10 may include both wired and wireless communication devices or apparatus 50 suitable for implementing embodiments of the invention.

For example, the system shown in FIG. 3 shows a mobile telephone network 11 and a representation of the internet 28. Connectivity to the internet 28 may include, but is not limited to, long range wireless connections, short range wireless connections, and various wired connections including, but not limited to, telephone lines, cable lines, power lines, and similar communication pathways.

The example communication devices shown in the system 10 may include, but are not limited to, an electronic device or apparatus 50, a combination of a personal digital assistant (PDA) and a mobile telephone 14, a PDA 16, an integrated messaging device (IMD) 18, a desktop computer 20, a notebook computer 22. The apparatus 50 may be stationary or mobile when carried by an individual who is moving. The apparatus 50 may also be located in a mode of transport including, but not limited to, a car, a truck, a taxi, a bus, a train, a boat, an airplane, a bicycle, a motorcycle or any similar suitable mode of transport.

Some or further apparatuses may send and receive calls and messages and communicate with service providers through a wireless connection 25 to a base station 24. The base station 24 may be connected to a network server 26 that allows communication between the mobile telephone network 11 and the internet 28. The system may include additional communication devices and communication devices of various types.

The communication devices may communicate using various transmission technologies including, but not limited to, code division multiple access (CDMA), global systems for mobile communications (GSM), universal mobile telecommunications system (UMTS), time divisional multiple access (TDMA), frequency division multiple access (FDMA), transmission control protocol-internet protocol (TCP-IP), short messaging service (SMS), multimedia messaging service (MMS), email, instant messaging service

(IMS), Bluetooth, IEEE 802.11 and any similar wireless communication technology. A communications device involved in implementing various embodiments of the present invention may communicate using various media including, but not limited to, radio, infrared, laser, cable connections, and any suitable connection.

With respect to FIG. 4a, a block diagram of a video encoder suitable for carrying out embodiments of the invention is shown. Furthermore, with respect to FIGS. 5a and 5b, the operation of the encoder exemplifying embodiments of the invention specifically with respect to construction of the list of candidate predictions is shown as a flow diagram.

FIG. 4a shows the encoder as comprising a pixel predictor 302, prediction error encoder 303 and prediction error decoder 304. FIG. 4a also shows an embodiment of the pixel predictor 302 as comprising an inter-predictor 306, an intra-predictor 308, a mode selector 310, a filter 316, and a reference frame memory 318. In this embodiment the mode selector 310 comprises a block processor 381 and a cost evaluator 382. The encoder may further comprise an entropy encoder 330 for entropy encoding the bit stream.

FIG. 4b depicts an embodiment of the inter predictor 306. The inter predictor 306 comprises a reference frame selector 360 for selecting reference frame or frames, a motion vector definer 361, a prediction list modifier 363 and a motion vector selector 364. These elements or some of them may be part of a prediction processor 362 or they may be implemented by using other means.

The pixel predictor 302 receives the image 300 to be encoded at both the inter-predictor 306 (which determines the difference between the image and a motion compensated reference frame 318) and the intra-predictor 308 (which determines a prediction for an image block based only on the already processed parts of the current frame or picture). The output of both the inter-predictor and the intra-predictor may be passed to the mode selector 310. The intra-predictor 308 may have more than one intra-prediction modes. Hence, each mode may perform the intra-prediction and provide the predicted signal to the mode selector 310. The mode selector 310 also receives a copy of the image 300.

The mode selector 310 determines which encoding mode to use to encode the current block. If the mode selector 310 decides to use an inter-prediction mode it will pass the output of the inter-predictor 306 to the output of the mode selector 310. If the mode selector 310 decides to use an intra-prediction mode it will pass the output of one of the intra-predictor modes to the output of the mode selector 310.

The output of the mode selector is passed to a first summing device 321. The first summing device may subtract the pixel predictor 302 output from the image 300 to produce a first prediction error signal 320 which is input to the prediction error encoder 303.

The pixel predictor 302 further receives from a preliminary reconstructor 339 the combination of the prediction representation of the image block 312 and the output 338 of the prediction error decoder 304. The preliminary reconstructed image 314 may be passed to the intra-predictor 308 and to a filter 316. The filter 316 receiving the preliminary representation may filter the preliminary representation and output a final reconstructed image 340 which may be saved in a reference frame memory 318. The reference frame memory 318 may be connected to the inter-predictor 306 to be used as the reference image against which the future image 300 is compared in inter-prediction operations.

The operation of the pixel predictor 302 may be configured to carry out any known pixel prediction algorithm known in the art.

The pixel predictor **302** may also comprise a filter **385** to filter the predicted values before outputting them from the pixel predictor **302**.

The operation of the prediction error encoder **302** and prediction error decoder **304** will be described hereafter in further detail. In the following examples the encoder generates images in terms of 16×16 pixel macroblocks which go to form the full image or picture. Thus, for the following examples the pixel predictor **302** outputs a series of predicted macroblocks of size 16×16 pixels and the first summing device **321** outputs a series of 16×16 pixel residual data macroblocks which may represent the difference between a first macro-block in the image **300** against a predicted macro-block (output of pixel predictor **302**). It would be appreciated that other size macro blocks may be used.

The prediction error encoder **303** comprises a transform block **342** and a quantizer **344**. The transform block **342** transforms the first prediction error signal **320** to a transform domain. The transform is, for example, the DCT transform. The quantizer **344** quantizes the transform domain signal, e.g. the DCT coefficients, to form quantized coefficients.

The prediction error decoder **304** receives the output from the prediction error encoder **303** and performs the opposite processes of the prediction error encoder **303** to produce a decoded prediction error signal **338** which when combined with the prediction representation of the image block **312** at the second summing device **339** produces the preliminary reconstructed image **314**. The prediction error decoder may be considered to comprise a dequantizer **346**, which dequantizes the quantized coefficient values, e.g. DCT coefficients, to reconstruct the transform signal and an inverse transformation block **348**, which performs the inverse transformation to the reconstructed transform signal wherein the output of the inverse transformation block **348** contains reconstructed block(s). The prediction error decoder may also comprise a macroblock filter (not shown) which may filter the reconstructed macroblock according to further decoded information and filter parameters.

In the following the operation of an example embodiment of the inter predictor **306** will be described in more detail. The inter predictor **306** receives the current block for inter prediction. It is assumed that for the current block there already exists one or more neighbouring blocks which have been encoded and motion vectors have been defined for them. For example, the block on the left side and/or the block above the current block may be such blocks. Spatial motion vector predictions for the current block can be formed e.g. by using the motion vectors of the encoded neighbouring blocks and/or of non-neighbour blocks in the same slice or frame, using linear or non-linear functions of spatial motion vector predictions, using a combination of various spatial motion vector predictors with linear or non-linear operations, or by any other appropriate means that do not make use of temporal reference information. It may also be possible to obtain motion vector predictors by combining both spatial and temporal prediction information of one or more encoded blocks. These kinds of motion vector predictors may also be called as spatio-temporal motion vector predictors.

Reference frames used in encoding the neighbouring blocks have been stored to the reference frame memory **404**. The reference frames may be short term references or long term references and each reference frame may have a unique index indicative of the location of the reference frame in the reference frame memory. When a reference frame is no longer used as a reference frame it may be removed from the

reference frame memory or marked as a non-reference frame wherein the storage location of that reference frame may be occupied for a new reference frame. In addition to the reference frames of the neighbouring blocks the reference frame selector **360** may also select one or more other frames as potential reference frames and store them to the reference frame memory.

Motion vector information of encoded blocks is also stored into the memory so that the inter predictor **306** is able to retrieve the motion vector information when processing motion vector candidates for the current block.

In some embodiments the motion vectors are stored into one or more lists. For example, motion vectors of unidirectionally predicted frames (e.g. P-frames) may be stored to a list called as list 0. For bi-directionally predicted frames (e.g. B-frames) there may be two lists (list 0 and list 1) and for multi-predicted frames there may be more than two lists. Reference frame indices possibly associated with the motion vectors may also be stored in one or more lists.

In some embodiments there may be two or more motion vector prediction procedures and each procedure may have its own candidate set creation process. In one procedure, only the motion vector values are used. In another procedure, which may be called as a Merge Mode, each candidate element may comprise 1) The information whether 'block was uni-predicted using only list0' or 'block was uni-predicted using only list1' or 'block was bi-predicted using list0 and list1' 2) motion vector value for list0 3) Reference picture index in list0 4) motion vector value for list1 5) Reference picture index list1. Therefore, whenever two prediction candidates are to be compared, not only the motion vector values are compared, but also the five values mentioned above may be compared to determine whether they correspond with each other or not. On the other hand, if any of the comparisons indicate that the prediction candidates do not have equal motion information, no further comparisons need be performed.

The motion vector definer **361** defines candidate motion vectors for the current frame by using one or more of the motion vectors of one or more neighbour blocks and/or other blocks of the current block in the same frame and/or co-located blocks and/or other blocks of the current block in one or more other frames. These candidate motion vectors can be called as a set of candidate predictors or a predictor set. Each candidate predictor thus represents the motion vector of one or more already encoded block. In some embodiments the motion vector of the candidate predictor is set equal to the motion vector of a neighbour block for the same list if the current block and the neighbour block refer to the same reference frames for that list. Also for temporal prediction there may be one or more previously encoded frames wherein motion vectors of a co-located block or other blocks in a previously encoded frame can be selected as candidate predictors for the current block. The temporal motion vector predictor candidate can be generated by any means that make use of the frames other than the current frame.

The candidate motion vectors can also be obtained by using more than one motion vector of one or more other blocks such as neighbour blocks of the current block and/or co-located blocks in one or more other frames. As an example, any combination of the motion vector of the block to the left of the current block, the motion vector of the block above the current block, and the motion vector of the block at the up-right corner of the current block may be used (i.e. the block to the right of the block above the current block). The combination may be a median of the motion vectors or

13

calculated by using other formulas. For example, one or more of the motion vectors to be used in the combination may be scaled by a scaling factor, an offset may be added, and/or a constant motion vector may be added. In some embodiments the combined motion vector is based on both temporal and spatial motion vectors, e.g. the motion vector of one or more of the neighbour block or other block of the current block and the motion vector of a co-located block or other block in another frame.

If a neighbour block does not have any motion vector information a default motion vector such as a zero motion vector may be used instead.

FIG. 9 illustrates an example of a coding unit 900 and some neighbour blocks 901-905 of the coding unit. As can be seen from FIG. 9, if the coding unit 900 represents the current block, the neighbouring blocks 901-905 labelled A0, A1, B0, B1 and B2 could be such neighbour blocks which may be used when obtaining the candidate motion vectors.

Creating additional or extra motion vector predictions based on previously added predictors may be needed when the current number of candidates is limited or insufficient. This kind of creating additional candidates can be performed by combining previous two predictions and/or processing one previous candidate by scaling or adding offset and/or adding a zero motion vector with various reference indices. Hence, the motion vector definer 361 may examine how many motion vector candidates can be defined and how many potential candidate motion vectors exist for the current block. If the number of potential motion vector candidates is smaller than a threshold, the motion vector definer 361 may create additional motion vector predictions.

In some embodiments the combined motion vector can be based on motion vectors in different lists. For example, one motion vector may be defined by combining one motion vector from the list 0 and one motion vector from the list 1 e.g. when the neighbouring or co-located block is a bi-directionally predicted block and there exists one motion vector in the list 0 and one motion vector in the list 1 for the bi-directionally predicted block.

To distinguish the current block from the encoded/decoded blocks the motion vectors of which are used as candidate motion vectors, those encoded/decoded blocks are also called as reference blocks in this application.

In some embodiments not only the motion vector information of the reference block(s) is obtained (e.g. by copying) but also a reference index of the reference block in the reference picture list may be copied to the candidate list. The information whether the block was uni-predicted using only list0 or the block was uni-predicted using only list1 or the block was bi-predicted using list0 and list1 may also be copied. The candidate list may also be called as a candidate set or a set of motion vector prediction candidates.

FIG. 6a illustrates an example of spatial and temporal prediction of a prediction unit. There is depicted the current block 601 in the frame 600 and a neighbour block 602 which already has been encoded. The motion vector definer 361 has defined a motion vector 603 for the neighbour block 602 which points to a block 604 in the previous frame 605. This motion vector can be used as a potential spatial motion vector prediction 610 for the current block. FIG. 6a depicts that a co-located block 606 in the previous frame 605, i.e. the block at the same location than the current block but in the previous frame, has a motion vector 607 pointing to a block 609 in another frame 608. This motion vector 607 can be used as a potential temporal motion vector prediction-611 for the current frame.

14

FIG. 6b illustrates another example of spatial and temporal prediction of a prediction unit. In this example the block 606 of the previous frame 605 uses bi-directional prediction based on the block 609 of the frame preceding the frame 605 and on the block 612 succeeding the current frame 600. The temporal motion vector prediction for the current block 601 may be formed by using both the motion vectors 607, 614 or either of them.

The operation of the prediction list modifier 363 will now be described in more detail with reference to the flow diagram of FIGS. 5a and 5b. The prediction list modifier 363 initializes a motion vector prediction list to default values in block 500 of FIG. 5a. The prediction list modifier 363 may also initialize a list index to an initial value such as zero. Then, in block 501 the prediction list modifier checks whether there are any motion vector candidates to process. If there is at least one motion vector candidate in the predictor set for processing, the prediction list modifier 363 generates the next motion vector candidate which may be a temporal motion vector or a spatial motion vector. The comparison can be an identity/equivalence check or comparing the (absolute) difference against a threshold or any other similarity metric.

In the following, a merge process for motion information coding according to an example embodiment will be described in more detail. The encoder creates a list of motion prediction candidates from which one of the candidates is to be signalled as the motion information for the current coding unit or prediction unit. The motion prediction candidates may consist of several spatial motion predictions and a temporal motion prediction. The spatial candidates can be obtained from the motion information of e.g. the spatial neighbour blocks A0, A1, B0, B1, B2, whose motion information is used as spatial candidate motion predictions. The temporal motion prediction candidate may be obtained by processing the motion of a block in a frame other than the current frame. In this example embodiment, the encoder operations to construct the merge list for the spatial candidates may include the following. The operations may be carried out by the prediction list modifier 363, for example.

A maximum number of spatial motion prediction candidates to be included in the merge list may be defined. This maximum number may have been stored, for example, to the memory 58 of the apparatus 50, or to another appropriate place. It is also possible to determine the maximum number by using other means, or it may be determined in the software of the encoder of the apparatus 50.

In some embodiments the maximum number of spatial motion prediction candidates to be included in the merge list is four but in some embodiments the maximum number may be less than four or greater than four.

In this example the spatial motion prediction candidates are the spatial neighbour blocks A0, A1, B0, B1, B2. The spatial motion vector prediction candidate A1 is located on the left side of the prediction unit when the encoding/decoding order is from left to right and from top to bottom of the frame, slice or another entity to be encoded/decoded. Respectively, the spatial motion vector prediction candidate B1 is located above the prediction unit. third; the spatial motion vector prediction candidate B0 is on the right side of the spatial motion vector prediction candidate B1; the spatial motion vector prediction candidate A0 is below the spatial motion vector prediction candidate A1; and the spatial motion vector prediction candidate B2 is located on the same column than spatial motion vector prediction candidate A1 and on the same row than the spatial motion vector prediction candidate B1. In other words, the spatial motion

15

vector prediction candidate B2 is cornerwise neighbouring the prediction unit as can be seen e.g. from FIG. 9.

These spatial motion prediction candidates can be processed in a predetermined order, for example, A1, B1, B0, A0 and B2. The first spatial motion prediction candidate to be selected for further examination is thus A1. Before further examination is performed for the selected spatial motion prediction candidate, it may be determined whether the merge list already contains a maximum number of spatial motion prediction candidates. Hence, the prediction list modifier 363 compares 502 the number of spatial motion prediction candidates in the merge list with the maximum number, and if the number of spatial motion prediction candidates in the merge list is not less than the maximum number, the selected spatial motion prediction candidate is not included in the merge list and the process of constructing the merge list can be stopped 526. On the other hand, if the number of spatial motion prediction candidates in the merge list is less than the maximum number, a further analyses of the selected spatial motion prediction candidate is performed (blocks 504-522).

For all the spatial motion prediction candidates for which the further analyses is to be performed, some or all of the following conditions below may be tested for determining whether to include the spatial motion prediction candidate in the merge list.

The prediction list modifier 363 examines 504 if the prediction unit or block covering the spatial motion prediction candidate block is not available for motion prediction. If so, the candidate is not included in the merge list. The reason that the block is not available may be that the block is either coded in intra mode or resides in a different slice or outside of the picture area.

In addition to the common conditions above, for each spatial motion prediction candidate, if any of the following conditions holds, then the candidate is not included in the merge list, otherwise, it is included.

The prediction list modifier 363 determines 506 which spatial motion prediction candidate of the set of spatial motion prediction candidates is in question. If the spatial motion prediction candidate is the block A1, one or more of the following conditions may be examined 508, 510 to determine whether to include this spatial motion prediction candidate in the merge list or not. If the current coding unit 100 is vertically split into two rectangle prediction units 103, 104 as depicted in FIG. 10b and the current prediction unit is the second prediction unit 104 in the coding/decoding order (508), this spatial motion prediction candidate is not included in the merge list. If the current coding unit 100 is not vertically split into two rectangle prediction units but it is horizontally split into two rectangle prediction units 101, 102 as depicted in FIG. 10a and the current prediction unit is the second prediction unit in the coding/decoding order and the block A1 has the same motion information as the block B1 (510), this spatial motion prediction candidate (block A1) is not included in the merge list. In the example of FIG. 10a the second prediction unit is the lower prediction unit 102 of the coding unit 100 and in the example of FIG. 10b the second prediction unit is the rightmost prediction unit 104 of the coding unit 100. If none of the conditions above is fulfilled the block A1 is included in the merge list as a spatial motion prediction candidate (524).

If the spatial motion prediction candidate is the block B1, one or more of the following conditions may be examined 512, 514 to determine whether to include this spatial motion prediction candidate in the merge list or not. If the current coding unit 100 is horizontally split into two rectangle

16

prediction units 101, 102 as depicted in FIG. 10a and the current prediction unit is the second prediction unit 104 in the coding/decoding order (512), this spatial motion prediction candidate is not included in the merge list. If the current coding unit 100 is not horizontally split into two rectangle prediction units and if the block B1 has the same motion information than the block A1 (514), this spatial motion prediction candidate (block B1) is not included in the merge list. If none of the conditions above is fulfilled the block B1 is included in the merge list as a spatial motion prediction candidate (524).

If the spatial motion prediction candidate is the block B0, this spatial motion prediction candidate is not included in the merge list if the block B0 has the same motion information than the block B1 (516). Otherwise, if the number of spatial motion prediction candidates in the merge list is less than the maximum number of spatial motion prediction candidates, this spatial motion prediction candidate (block B0) is included in the merge list (524).

If the spatial motion prediction candidate is the block A0, this spatial motion prediction candidate is not included in the merge list if the block A0 has the same motion information than the block A1 (518). Otherwise, if the number of spatial motion prediction candidates in the merge list is less than the maximum number of spatial motion prediction candidates, this spatial motion prediction candidate (block A0) is included in the merge list (524).

If the spatial motion prediction candidate is the block B2, this spatial motion prediction candidate is not included in the merge list if the maximum number of spatial motion prediction candidates is four and the other blocks A0, A1, B0, and B1 are all decided to be included in the merge list (520). Otherwise, if the number of spatial motion prediction candidates in the merge list is less than the maximum number of spatial motion prediction candidates, the block B2 is not included in the merge list if the block B2 has the same motion information than the block B1 or the block A1 (522).

Then, after processing the blocks A1, B1, B0, A0 and B2 and including a subset of them in the merge list based on the above described conditions, no more redundancy check between these candidates are performed and remaining temporal motion prediction candidate and/or other possible additional candidates may be processed.

Comparing two blocks whether they have the same motion may be performed by comparing all the elements of the motion information, namely 1) The information whether 'the prediction unit is uni-predicted using only reference picture list0' or 'the prediction unit is un-predicted using only reference picture list1' or 'the prediction unit is bi-predicted using both reference picture list0 and list1' 2) Motion vector value corresponding to the reference picture list0 3) Reference picture index in the reference picture list0 4) Motion vector value corresponding to the reference picture list1 5) Reference picture index in the reference picture list1.

In some embodiments similar restrictions for comparing candidate pairs can be applied if the current coding unit is coded/decoded by splitting into four or any number of prediction units.

The maximum number of merge list candidates can be any non-zero value. In the example above the merger list candidates were the spatial neighbour blocks A0, A1, B0, B1, B2 and the temporal motion prediction candidate, but there may be more than one temporal motion prediction candidate and also other spatial motion prediction candidates than the

spatial neighbour blocks. In some embodiments there may also be other spatial neighbour blocks than the blocks A0, A1, B0, B1, B2.

It is also possible that the maximum number of spatial motion prediction candidates included in the list can be different than four.

In some embodiments the maximum number of merge list candidates and maximum number of spatial motion prediction candidates included in the list can depend on whether a temporal motion vector candidate is included in the list or not.

A different number of spatial motion prediction candidates located at various locations in the current frame can be processed. The locations can be the same as or different than A1, B1, B0, A0 and B2.

The decision of including which spatial motion prediction candidates in the list can be realized in two steps. In the first step, some of the candidates are eliminated by checking whether the candidate block is available and/or the candidate block's prediction mode is intra and/or whether the current block is a second prediction unit of a coding unit coded with two prediction units and the candidate has the same motion with the first prediction unit. In the second step, remaining candidates are examined and some or all of them are included in the merge list. The examination in the second step does not include comparing motion information of each possible candidate pair but includes a subset of the possible comparison combinations.

The decisions for the candidates can be taken in any order of A1, B1, B0, A0 and B2 or independently in parallel.

For each candidate and/or a subset of the candidates, the following conditions may also be checked: Whether the candidate block has the same motion as the first prediction unit of the current coding unit when the current coding unit is split into two rectangle prediction units and the current prediction unit is the second prediction unit in the coding/decoding order.

Additional conditions related to various properties of current and/or previous slices and/or current and/or neighbour blocks can be utilized for determining whether to include a candidate in the list.

Motion comparison can be realized by comparing a subset of the whole motion information. For example, only the motion vector values for some or all reference picture lists and/or reference indices for some or all reference picture lists and/or an identifier value assigned to each block to represent its motion information can be compared. The comparison can be an identity check or an equivalence check or comparing the (absolute) difference against a threshold or any other similarity metric.

Conditions for deciding whether a candidate is to be included in the list can include motion information comparison with any subset of the candidates as long as not all possible candidate pairs are compared eventually.

Deciding whether a temporal motion vector candidate is to be included in the list can be based on comparing its motion information with motion information of a subset of the spatial motion vector prediction candidates.

When comparing motion information of two blocks, motion information of additional blocks can be considered too. For example, when comparing the block B2 and the block A1 (illustrated in FIG. 12) are checked whether they have the same motion; and when comparing the block B2 and the block B1, all the blocks between the block B2 and the block B1 (illustrated in FIG. 12) are checked whether they have the same motion. This embodiment can be implemented so

that the right-most block of each prediction unit or all blocks of each prediction unit may store the information of how many consecutive blocks to the above have the same motion information. Also the bottom-most block of each prediction unit or all blocks of each prediction unit may store the information of how many consecutive blocks to the left have the same motion information. Using this information the condition for not including B0 in the list can be realized by checking if the number of consecutive blocks with the same motion to the left of B0 is greater than 0. The condition for not including A0 in the list can be realized by checking if the number of consecutive blocks with same motion to the above of A0 is greater than 0. The conditions for not including B2 can be modified as follows:

It is not examined whether the block B2 has same motion as the block B1 or whether the block B2 has same motion as the block A1, but how many consecutive blocks exists to the left of the block B1 with the same motion than the block B1 and/or how many consecutive blocks exist above the block A1 with the same motion. If the number of consecutive blocks with the same motion to the left of the block B1 is greater than the number of blocks between B2 and B1, or if the number of consecutive blocks with the same motion above the block A1 is greater than the number of blocks between the block B2 and the block A1, the block B2 is not included in the merge list.

If the above implementation is used, the value of how many consecutive blocks to the left/above have the same motion information can be determined by direct comparison of motion information or checking the prediction mode and/or the merge index if the block employs a merge process.

When coding/decoding the selected merge index, the information whether the merge process is employed for coding/decoding a Skip mode coding unit or an Inter Merge mode prediction unit can be taken into account. For example, if a context adaptive binary arithmetic coder (CABAC) is used for entropy coding/decoding, different contexts can be used for the bins depending on the coding mode (Skip mode or inter merge mode) of the current block. Furthermore, assigning two contexts depending on whether the merge process is employed in a Skip mode coding unit or an inter Merge mode prediction unit can be applied for only the most significant bin of the merge index.

During the process of removal of redundant candidates, comparison between motion vector predictor candidates can also be based on any other information than the motion vector values. For example, it can be based on linear or non-linear functions of motion vector values, coding or prediction types of the blocks used to obtain the motion information, block size, the spatial location in the frame/ (largest) coding unit/macroblock, the information whether blocks share the same motion with a block, the information whether blocks are in the same coding/prediction unit, etc.

The following pseudo code illustrates an example embodiment of the invention for constructing the merging list.

Inputs to this process are

- a luma location (xP, yP) specifying the top-left luma sample of the current prediction unit relative to the top-left sample of the current picture;
- variables specifying the width and the height of the prediction unit for luma, nPSW and nPSH; and
- a variable PartIdx specifying the index of the current prediction unit within the current coding unit.

Outputs of this process are (with N being replaced by A0, A1, B0, B1 or B2 and with X being replaced by 0 or 1)

19

the availability flags availableFlagN of the neighbouring prediction units,
the reference indices refIdxLXN of the neighbouring prediction units,
the prediction list utilization flags predFlagLXN of the neighbouring prediction units,
the motion vectors mvLXN of the neighbouring prediction units.

For the derivation of availableFlagN, with N being A₀, A₁, B₀, B₁ or B₂ and (xN, yN) being (xP-1, yP+nPSH), (xP-1, yP+nPSH-1), (xP+nPSW, yP-1), (xP+nPSW-1, yP-1) or (xP-1, yP-1), the following applies.

If one of the following conditions is true, the availableFlagN is set equal to 0, both components mvLXN are set equal to 0, refIdxLXN and predFlagLX[xN, yN] of the prediction unit covering luma location (xN, yN) are assigned respectively to mvLXN, refIdxLXN and predFlagLXN.

N is equal to B₂ and availableFlagA₀+availableFlagA₁+availableFlagB₀+availableFlagB₁ is equal to 4.

The prediction unit covering luma location (xN, yN) is not available or PredMode is MODE_INTRA.

N is equal to A₁ and Part Mode of the current prediction unit is PART_Nx2N or PART_nLx2N or PART_nRx2N and PartIdx is equal to 1.

N is equal to A₁ and Part Mode of the current prediction unit is PART_2NxN or PART_2NxN or PART_2NxN and PartIdx is equal to 1 and the prediction units covering luma location (xP+nPSW-1, yP-1) (N=B₁) and luma location (xN, yN) (Cand. N) have identical motion parameters:

mvLX[xP+nPSW-1, yP-1]=mvLX[xN, yN]
refIdxLX[xP+nPSW-1, yP-1]=refIdxLX[xN, yN]
predFlagLX[xP+nPSW-1, yP-1]=predFlagLX[xN, yN]

N is equal to B₁ and Part Mode of the current prediction unit is 2NxN or PART_2NxN or PART_2NxN and PartIdx is equal to 1.

N is equal to B₁ and the prediction units covering luma location (xP-1, yP+nPSH-1) (N=A₁) and luma location (xN, yN) (Cand. N) have identical motion parameters:

mvLX[xP-1, yP+nPSH-1]=mvLX[xN, yN]
refIdxLX[xP-1, yP+nPSH-1]=refIdxLX[xN, yN]
predFlagLX[xP-1, yP+nPSH-1]=predFlagLX[xN, yN]

N is equal to B₀ and the prediction units covering luma location (xP+nPSW-1, yP-1) (N=B₁) and luma location (xN, yN) (Cand. N) have identical motion parameters:

mvLX[xP+nPSW-1, yP-1]=mvLX[xN, yN]
refIdxLX[xP+nPSW-1, yP-1]=refIdxLX[xN, yN]
predFlagLX[xP+nPSW-1, yP-1]=predFlagLX[xN, yN]

N is equal to A₀ and the prediction units covering luma location (xP-1, yP+nPSH-1) (N=A₁) and luma location (xN, yN) (Cand. N) have identical motion parameters:

mvLX[xP-1, yP+nPSH-1]=mvLX[xN, yN]
refIdxLX[xP-1, yP+nPSH-1]=refIdxLX[xN, yN]
predFlagLX[xP-1, yP+nPSH-1]=predFlagLX[xN, yN]

N is equal to B₂ and the prediction units covering luma location (xP+nPSW-1, yP-1) (N=B₁) and luma location (xN, yN) (Cand. N) have identical motion parameters:

20

mvLX[xP+nPSW-1, yP-1]=mvLX[xN, yN]
refIdxLX[xP+nPSW-1, yP-1]=refIdxLX[xN, yN]
predFlagLX[xP+nPSW-1, yP-1]=predFlagLX[xN, yN]

N is equal to B₂ and the prediction units covering luma location (xP-1, yP+nPSH-1) (N=A₁) and luma location (xN, yN) (Cand. N) have identical motion parameters:

mvLX[xP-1, yP+nPSH-1]=mvLX[xN, yN]
refIdxLX[xP-1, yP+nPSH-1]=refIdxLX[xN, yN]
predFlagLX[xP-1, yP+nPSH-1]=predFlagLX[xN, yN]

Part Mode of the current prediction unit is PART_NxN and PartIdx is equal to 3 and the prediction units covering luma location (xP-1, yP) (PartIdx=2) and luma location (xP-1, yP-1) (PartIdx=0) have identical motion parameters:

mvLX[xP-1, yP]=mvLX[xP-1, yP-1]
refIdxLX[xP-1, yP]=refIdxLX[xP-1, yP-1]
predFlagLX[xP-1, yP]=predFlagLX[xP-1, yP-1]

and the prediction units covering luma location (xP, yP-1) (PartIdx=1) and luma location (xN, yN) (Cand. N) have identical motion parameters:

mvLX[xP, yP-1]=mvLX[xN, yN]
refIdxLX[xP, yP-1]=refIdxLX[xN, yN]
predFlagLX[xP, yP-1]=predFlagLX[xN, yN]

Part Mode of the current prediction unit is PART_NxN and PartIdx is equal to 3 and the prediction units covering luma location (xP, yP-1) (PartIdx=1) and luma location (xP-1, yP-1) (PartIdx=0) have identical motion parameters:

mvLX[xP, yP-1]=mvLX[xP-1, yP-1]
refIdxLX[xP, yP-1]=refIdxLX[xP-1, yP-1]
predFlagLX[xP, yP-1]=predFlagLX[xP-1, yP-1]

and the prediction units covering luma location (xP-1, yP) (PartIdx=2) and luma location (xN, yN) (Cand. N) have identical motion parameters:

mvLX[xP-1, yP]=mvLX[xN, yN]
refIdxLX[xP-1, yP]=refIdxLX[xN, yN]
predFlagLX[xP-1, yP]=predFlagLX[xN, yN]

Otherwise, availableFlagN is set equal to 1 and the variables mvLX[xN, yN], refIdxLX[xN, yN] and predFlagLX[xN, yN] of the prediction unit covering luma location (xN, yN) are assigned respectively to mvLXN, refIdxLXN and predFlagLXN.

For the motion vector predictor candidate list generation process, each list candidate can include more information than the motion vector value, such as the reference lists used, the reference frames used in each list and motion vector for each list.

When all motion vector candidates have been examined, one motion vector is selected to be used as the motion vector for the current block. The motion vector selector 364 may examine different motion vectors in the list and determine which motion vector provides the most efficient encoding result, or the selection of the motion vector may be based on to other criteria as well. Information of the selected motion vector is provided for the mode selector for encoding and transmission to the decoder or for storage when the mode selector determines to use inter prediction for the current block. The information may include the index of the motion vector in the list, and/or motion vector parameters or other appropriate information.

The selected motion vector and the block relating to the motion vector is used to generate the prediction representation of the image block 312 which is provided as the output of the mode selector. The output may be used by the first

21

summing device **321** to produce the first prediction error signal **320**, as was described above.

The selected motion vector predictor candidate can be modified by adding a motion vector difference or can be used directly as the motion vector of the block. Moreover, after the motion compensation is performed by using the selected motion vector predictor candidate, the residual signal of the block can be transform coded or skipped to be coded.

Although the embodiments above have been described with respect to the size of the macroblock being 16×16 pixels, it would be appreciated that the methods and apparatus described may be configured to handle macroblocks of different pixel sizes.

In the following the operation of an example embodiment of the decoder **600** is depicted in more detail with reference to FIG. 7.

At the decoder side similar operations are performed to reconstruct the image blocks. FIG. 7 shows a block diagram of a video decoder **700** suitable for employing embodiments of the invention and FIGS. **8a** and **8b** show a flow diagram of an example of a method in the video decoder. The bitstream to be decoded may be received from the encoder, from a network element, from a storage medium or from another source. The decoder is aware of the structure of the bitstream so that it can determine the meaning of the entropy coded codewords and may decode the bitstream by an entropy decoder **701** which performs entropy decoding on the received signal. The entropy decoder thus performs the inverse operation to the entropy encoder **330** of the encoder described above. The entropy decoder **701** outputs the results of the entropy decoding to a prediction error decoder **702** and a pixel predictor **704**.

In some embodiments the entropy coding may not be used but another channel encoding may be in use, or the encoded bitstream may be provided to the decoder **700** without channel encoding. The decoder **700** may comprise a corresponding channel decoder to obtain the encoded codewords from the received signal.

The pixel predictor **704** receives the output of the entropy decoder **701**. The output of the entropy decoder **701** may include an indication on the prediction mode used in encoding the current block. A predictor selector **714** within the pixel predictor **704** determines that an intra-prediction or an inter-prediction is to be carried out. The predictor selector **714** may furthermore output a predicted representation of an image block **716** to a first combiner **713**. The predicted representation of the image block **716** is used in conjunction with the reconstructed prediction error signal **712** to generate a preliminary reconstructed image **718**. The preliminary reconstructed image **718** may be used in the predictor **714** or may be passed to a filter **720**. The filter **720**, if used, applies a filtering which outputs a final reconstructed signal **722**. The final reconstructed signal **722** may be stored in a reference frame memory **724**, the reference frame memory **724** further being connected to the predictor **714** for prediction operations.

Also the prediction error decoder **702** receives the output of the entropy decoder **701**. A dequantizer **792** of the prediction error decoder **702** may dequantize the output of the entropy decoder **701** and the inverse transform block **793** may perform an inverse transform operation to the dequantized signal output by the dequantizer **792**. The output of the entropy decoder **701** may also indicate that prediction error signal is not to be applied and in this case the prediction error decoder produces an all zero output signal.

22

The decoder selects the 16×16 pixel residual macroblock to reconstruct. This residual macroblock is also called as a current block.

The decoder may receive information on the encoding mode used in encoding of the current block. The indication is decoded, when necessary, and provided to the reconstruction processor **791** of the prediction selector **714**. The reconstruction processor **791** examines the indication and selects one of the intra-prediction mode(s), if the indication indicates that the block has been encoded using intra-prediction, or the inter-prediction mode, if the indication indicates that the block has been encoded using inter-prediction.

For inter-prediction mode the reconstruction processor **791** may comprise one or more elements corresponding to the prediction processor **362** of the encoder, such as a motion vector definer, a prediction list modifier and/or a motion vector selector.

The reconstruction processor **791** initializes a motion vector prediction list to default values in block **800**. As was the case in the encoding part, in this example the spatial motion prediction candidates are the spatial neighbour blocks **A0**, **A1**, **B0**, **B1**, **B2** and these spatial motion prediction candidates are processed in the same predetermined order than in the encoder: **A1**, **B1**, **B0**, **A0** and **B2**. The first spatial motion prediction candidate to be selected for further examination is thus **A1**. Before further examination is performed for the selected spatial motion prediction candidate, it is examined whether the merge list already contains a maximum number of spatial motion prediction candidates. If the number of spatial motion prediction candidates in the merge list is not less than the maximum number, the selected spatial motion prediction candidate is not included in the merge list and the process of constructing the merge list can be stopped **826**. On the other hand, if the number of spatial motion prediction candidates in the merge list is less than the maximum number, a further analyses of the selected spatial motion prediction candidate is performed (blocks **804-822**).

The decoder examines **804** if the prediction unit or block covering the spatial motion prediction candidate block is not available for motion prediction. If so, the candidate is not included in the merge list. The reason that the block is not available may be that the block is either coded in intra mode or resides in a different slice or outside of the picture area.

In addition to the common conditions above, for each spatial motion prediction candidate, if any of the following conditions holds, then the candidate is not included in the merge list, otherwise, it is included.

The decoder determines **806** which spatial motion prediction candidate of the set of spatial motion prediction candidates is in question. If the spatial motion prediction candidate is the block **A1**, one or more of the following conditions may be examined **808**, **810** to determine whether to include this spatial motion prediction candidate in the merge list or not. If the current coding unit **100** is vertically split into two rectangle prediction units **103**, **104** as depicted in FIG. **10b** and the current prediction unit is the second prediction unit **104** in the coding/decoding order (**808**), this spatial motion prediction candidate is not included in the merge list. If the current coding unit **100** is not vertically split into two rectangle prediction units but it is horizontally split into two rectangle prediction units **101**, **102** as depicted in FIG. **10a** and the current prediction unit is the second prediction unit in the coding/decoding order and the block **A1** has the same motion information as the block **B1** (**810**), this spatial motion prediction candidate (block **A1**) is not included in the merge list. In the example of FIG. **10a** the

23

second prediction unit is the lower prediction unit **102** of the coding unit **100** and in the example of FIG. **10b** the second prediction unit is the rightmost prediction unit **104** of the coding unit **100**. If none of the conditions above is fulfilled the block **A1** is included in the merge list as a spatial motion prediction candidate (**824**).

If the spatial motion prediction candidate is the block **B1**, one or more of the following conditions may be examined **812**, **814** to determine whether to include this spatial motion prediction candidate in the merge list or not. If the current coding unit **100** is horizontally split into two rectangle prediction units **101**, **102** as depicted in FIG. **10a** and the current prediction unit is the second prediction unit **104** in the coding/decoding order (**812**), this spatial motion prediction candidate is not included in the merge list. If the current coding unit **100** is not horizontally split into two rectangle prediction units and if the block **B1** has the same motion information than the block **A1** (**814**), this spatial motion prediction candidate (block **B1**) is not included in the merge list. If none of the conditions above is fulfilled the block **B1** is included in the merge list as a spatial motion prediction candidate (**824**).

If the spatial motion prediction candidate is the block **B0**, this spatial motion prediction candidate is not included in the merge list if the block **B0** has the same motion information than the block **B1** (**816**). Otherwise, if the number of spatial motion prediction candidates in the merge list is less than the maximum number of spatial motion prediction candidates, this spatial motion prediction candidate (block **B0**) is included in the merge list (**824**).

If the spatial motion prediction candidate is the block **A0**, this spatial motion prediction candidate is not included in the merge list if the block **A0** has the same motion information than the block **A1** (**818**). Otherwise, if the number of spatial motion prediction candidates in the merge list is less than the maximum number of spatial motion prediction candidates, this spatial motion prediction candidate (block **A0**) is included in the merge list (**824**).

If the spatial motion prediction candidate is the block **B2**, this spatial motion prediction candidate is not included in the merge list if the maximum number of spatial motion prediction candidates is four and the other blocks **A0**, **A1**, **B0**, and **B1** are all decided to be included in the merge list (**820**). Otherwise, if the number of spatial motion prediction candidates in the merge list is less than the maximum number of spatial motion prediction candidates, the block **B2** is not included in the merge list if the block **B2** has the same motion information than the block **B1** or the block **A1** (**822**).

Then, after processing the blocks **A1**, **B1**, **B0**, **A0** and **B2** and including a subset of them in the merge list based on the above described conditions, no more redundancy check between these candidates are performed and remaining temporal motion prediction candidate and/or other possible additional candidates may be processed.

When the merge list has been constructed the decoder may use **828** the indication of the motion vector received from the encoder to select the motion vector for decoding the current block. The indication may be, for example, an index to the merge list.

Basically, after the reconstruction processor **791** has constructed the merge list, it would correspond with the merge list constructed by the encoder if the reconstruction processor **791** has the same information available than the encoder had. If some information has been lost during transmission the information from the encoder to the decoder, it may affect the generation of the merge list in the decoder **700**.

24

The above examples describe the operation mainly in the merge mode but the encoder and decoder may also operate in other modes.

The embodiments of the invention described above describe the codec in terms of separate encoder and decoder apparatus in order to assist the understanding of the processes involved. However, it would be appreciated that the apparatus, structures and operations may be implemented as a single encoder-decoder apparatus/structure/operation. Furthermore in some embodiments of the invention the coder and decoder may share some or all common elements.

Although the above examples describe embodiments of the invention operating within a codec within an electronic device, it would be appreciated that the invention as described below may be implemented as part of any video codec. Thus, for example, embodiments of the invention may be implemented in a video codec which may implement video coding over fixed or wired communication paths.

Thus, user equipment may comprise a video codec such as those described in embodiments of the invention above.

It shall be appreciated that the term user equipment is intended to cover any suitable type of wireless user equipment, such as mobile telephones, portable data processing devices or portable web browsers.

Furthermore elements of a public land mobile network (PLMN) may also comprise video codecs as described above.

In general, the various embodiments of the invention may be implemented in hardware or special purpose circuits, software, logic or any combination thereof. For example, some aspects may be implemented in hardware, while other aspects may be implemented in firmware or software which may be executed by a controller, microprocessor or other computing device, although the invention is not limited thereto. While various aspects of the invention may be illustrated and described as block diagrams, flow charts, or using some other pictorial representation, it is well understood that these blocks, apparatus, systems, techniques or methods described herein may be implemented in, as non-limiting examples, hardware, software, firmware, special purpose circuits or logic, general purpose hardware or controller or other computing devices, or some combination thereof.

The embodiments of this invention may be implemented by computer software executable by a data processor of the mobile device, such as in the processor entity, or by hardware, or by a combination of software and hardware. Further in this regard it should be noted that any blocks of the logic flow as in the Figures may represent program steps, or interconnected logic circuits, blocks and functions, or a combination of program steps and logic circuits, blocks and functions. The software may be stored on such physical media as memory chips, or memory blocks implemented within the processor, magnetic media such as hard disk or floppy disks, and optical media such as for example DVD and the data variants thereof, CD.

The memory may be of any type suitable to the local technical environment and may be implemented using any suitable data storage technology, such as semiconductor based memory devices, magnetic memory devices and systems, optical memory devices and systems, fixed memory and removable memory. The data processors may be of any type suitable to the local technical environment, and may include one or more of general purpose computers, special purpose computers, microprocessors, digital signal processors (DSPs) and processors based on multi core processor architecture, as non limiting examples.

25

Embodiments of the inventions may be practiced in various components such as integrated circuit modules. The design of integrated circuits is by and large a highly automated process. Complex and powerful software tools are available for converting a logic level design into a semiconductor circuit design ready to be etched and formed on a semiconductor substrate.

Programs, such as those provided by Synopsys, Inc. of Mountain View, Calif. and Cadence Design, of San Jose, Calif. automatically route conductors and locate components on a semiconductor chip using well established rules of design as well as libraries of pre stored design modules. Once the design for a semiconductor circuit has been completed, the resultant design, in a standardized electronic format (e.g., Opus, GDSII, or the like) may be transmitted to a semiconductor fabrication facility or "fab" for fabrication.

The foregoing description has provided by way of exemplary and non-limiting examples a full and informative description of the exemplary embodiment of this invention. However, various modifications and adaptations may become apparent to those skilled in the relevant arts in view of the foregoing description, when read in conjunction with the accompanying drawings and the appended claims. However, all such and similar modifications of the teachings of this invention will still fall within the scope of this invention.

In the following some examples will be provided.

In some embodiments a method comprises:

receiving a block of pixels including a prediction unit; determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

In some embodiments the method comprises including neighbouring blocks of the received block of pixels in the set of spatial motion vector prediction candidates.

In some embodiments the method comprises constructing the set of spatial motion vector predictions by using motion vectors of one or more encoded blocks in a same frame than the block of pixels.

In some embodiments the method comprises selecting spatial motion vector prediction candidates from the set of spatial motion vector prediction candidates as the potential spatial motion vector prediction candidate in a predetermined order.

In some embodiments the method comprises comparing motion information of the potential spatial motion vector prediction candidate with motion information of at most one other spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates.

26

In some embodiments the method comprises prediction unit and a second prediction unit; and if so, excluding the potential spatial motion vector prediction candidate from the merge list if the prediction unit is the second prediction unit.

In some embodiments the method comprises

determining a maximum number of spatial motion vector prediction candidates to be included in a merge list; and limiting the number of spatial motion vector prediction candidates in the merge list smaller or equal to the maximum number.

In some embodiments the method comprises

examining, if the number of spatial motion vector prediction candidates in the merge list smaller than the maximum number;

if so, examining whether a prediction unit to which the potential spatial motion vector prediction candidate belongs is available for motion prediction;

if so, performing at least one of the following:

for the potential spatial motion vector prediction candidate on the left side of the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

the received block of pixels is vertically divided into a first prediction unit and a second prediction unit, and the prediction unit is the second prediction unit;

the received block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and if the prediction unit is the second prediction unit, and the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

for the potential spatial motion vector prediction candidate above the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

the received block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and the prediction unit is the second prediction unit;

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for the potential spatial motion vector prediction candidate, which is on the right side of the potential spatial motion vector prediction candidate above the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

for the potential spatial motion vector prediction candidate, which is below the potential spatial motion vector prediction candidate on the left side of the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for the potential spatial motion vector prediction candidate cornerwise neighbouring the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled: all the other potential spatial motion vector prediction candidates have been included in the merge list;

27

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit.

In some embodiments the method comprises including a temporal motion prediction candidate into the merge list.

In some embodiments the method comprises selecting one motion vector prediction candidate from the merge list to represent a motion vector prediction for the block of pixels.

In some embodiments a method according to the second aspect comprises:

receiving an encoded block of pixels including a prediction unit;

determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of another spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

In some embodiments the method comprises including neighbouring blocks of the received encoded block of pixels in the set of spatial motion vector prediction candidates.

In some embodiments the method comprises constructing the set of spatial motion vector predictions by using motion vectors of one or more decoded blocks in a same frame than the received encoded block of pixels.

In some embodiments the method comprises selecting spatial motion vector prediction candidates from the set of spatial motion vector prediction candidates as the potential spatial motion vector prediction candidate in a predetermined order.

In some embodiments the method comprises comparing motion information of the potential spatial motion vector prediction candidate with motion information of at most one other spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates.

In some embodiments the method comprises examining whether the received encoded block of pixels is divided into a first prediction unit and a second prediction unit; and if so, excluding the potential spatial motion vector prediction candidate from the merge list if the prediction unit is the second prediction unit.

In some embodiments the method comprises determining a maximum number of spatial motion vector prediction candidates to be included in a merge list; and limiting the number of spatial motion vector prediction candidates in the merge list smaller or equal to the maximum number.

28

In some embodiments the method comprises

examining, if the number of spatial motion vector prediction candidates in the merge list smaller than the maximum number;

if so, examining whether a prediction unit to which the potential spatial motion vector prediction candidate belongs is available for motion prediction;

if so, performing at least one of the following:

for the potential spatial motion vector prediction candidate on the left side of the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

the received encoded block of pixels is vertically divided into a first prediction unit and a second prediction unit, and the prediction unit is the second prediction unit;

the received encoded block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and if the prediction unit is the second prediction unit, and the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

for the potential spatial motion vector prediction candidate above the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

the received encoded block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and the prediction unit is the second prediction unit;

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for the potential spatial motion vector prediction candidate, which is on the right side of the potential spatial motion vector prediction candidate above the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

for the potential spatial motion vector prediction candidate, which is below the potential spatial motion vector prediction candidate on the left side of the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for the potential spatial motion vector prediction candidate cornerwise neighbouring the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

all the other potential spatial motion vector prediction candidates have been included in the merge list;

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit.

In some embodiments the method comprises including a temporal motion prediction candidate into the merge list.

29

In some embodiments the method comprises selecting one motion vector prediction candidate from the merge list to represent a motion vector prediction for the received encoded block of pixels.

In some embodiments an apparatus according to the third aspect comprises a processor and a memory including computer program code, the memory and the computer program code configured to, with the processor, cause the apparatus to:

receive a block of pixels

including a prediction unit;

determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

if at least one the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

In some embodiments an apparatus according to the fourth aspect comprises a processor and a memory including computer program code, the memory and the computer program code configured to, with the processor, cause the apparatus to:

receive an encoded block of pixels including a prediction unit;

determine a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

select a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determine a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

compare motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

exclude the first spatial motion vector prediction candidate from the merge list, if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other

In some embodiments a storage medium having stored thereon a computer program code a computer executable program code for use by an encoder, said program codes comprise instructions for use by an encoder, said program code comprises instructions for:

30

receiving a block of pixels including a prediction unit; determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

In some embodiments a storage medium having stored thereon a computer program code a computer executable program code for use by an encoder, said program codes comprise instructions for use by an encoder, said program code comprises instructions for:

receiving an encoded block of pixels including a prediction unit;

determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list.

In some embodiments an apparatus comprises:

means for receiving a block of pixels including a prediction unit;

means for selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

means for determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

means for comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

means for excluding the first spatial motion vector prediction candidate from the merge list, if at least one of the

31

comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other.

In some embodiments an apparatus comprises:

means for receiving an encoded block of pixels including a prediction unit;

means for determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

means for selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit;

means for determining a subset of spatial motion vector predictions based on the location of the block associated with the first spatial motion vector prediction candidate;

means for comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates;

means for excluding the first spatial motion vector prediction candidate from the merge list, if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other.

The invention claimed is:

1. A method comprising:

receiving a block of pixels including a prediction unit; determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit, where the merge list is constructed based on the motion information of the spatial motion vector prediction candidates and is utilized to identify motion vector prediction candidates of which one spatial motion vector prediction candidate from the merge list is signaled as the motion information for the prediction unit;

determining a subset of spatial motion vector prediction candidates based on a location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of spatial motion vector prediction candidates in the determined subset of spatial motion vector prediction candidates without making a comparison of each possible candidate pair from the set of spatial motion vector prediction candidates, wherein comparing comprises performing an equivalence check or comparing a difference in motion information to a threshold or other similarity metric;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list; and

32

causing information identifying the one spatial motion vector prediction candidate from the merge list to be transmitted to a decoder or to be stored.

2. The method according to claim 1 comprising selecting spatial motion vector prediction candidates from the set of spatial motion vector prediction candidates as the potential spatial motion vector prediction candidate in a predetermined order.

3. The method according to claim 1, comprising comparing motion information of the potential spatial motion vector prediction candidate with motion information of at most one other spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates.

4. The method according to claim 1 comprising examining whether the received block of pixels is divided into a first prediction unit and a second prediction unit; and if so, excluding the potential spatial motion vector prediction candidate from the merge list if the prediction unit is the second prediction unit.

5. The method according to claim 1, further comprising determining a maximum number of spatial motion vector prediction candidates to be included in a merge list; and limiting the number of spatial motion vector prediction candidates in the merge list smaller or equal to the maximum number.

6. The method according to claim 5 comprising:

examining, if the number of spatial motion vector prediction candidates in the merge list smaller than the maximum number;

if so, examining whether the prediction unit to which the potential spatial motion vector prediction candidate belongs is available for motion prediction;

if so, performing at least one of the following:

for a potential spatial motion vector prediction candidate on a left side of the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

the received block of pixels is vertically divided into a first prediction unit and a second prediction unit;

the received block of pixels is horizontally divided into a first prediction unit and a second prediction unit,

and if the prediction unit is the second prediction unit, and the potential spatial motion vector prediction candidate has essentially similar motion information than a spatial motion vector prediction candidate above the prediction unit;

for a potential spatial motion vector prediction candidate above the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

the received block of pixels is horizontally divided into a first prediction unit and a second prediction unit,

and the prediction unit is the second prediction unit; the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for a potential spatial motion vector prediction candidate, which is on a right side of the potential spatial motion vector prediction candidate above the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

33

for a potential spatial motion vector prediction candidate, which is below the potential spatial motion vector prediction candidate on the left side of the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for a potential spatial motion vector prediction candidate cornerwise neighbouring the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

- all the other potential spatial motion vector prediction candidates have been included in the merge list;
- the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;
- the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit.

7. The method according to claim 1 further comprising including a temporal motion prediction candidate into the merge list.

8. The method according to claim 1 comprising selecting one motion vector prediction candidate from the merge list to represent a motion vector prediction for the block of pixels.

9. A method comprising:

- receiving an encoded block of pixels including a prediction unit and information identifying a respective spatial motion vector prediction candidate from a merge list constructed by an encoder;
- determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;
- selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit, where the merge list is constructed based on the motion information of the spatial motion vector prediction candidates;
- determining a subset of spatial motion vector prediction candidates based on the location of the block associated with the first spatial motion vector prediction candidate;
- comparing motion information of the first spatial motion vector prediction candidate with motion information of another spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates without making a comparison of each possible candidate pair from the set of spatial motion vector prediction candidates, wherein comparing comprises performing an equivalence check or comparing a difference in motion information to a threshold or other similarity metric;
- if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list; and

34

selecting a spatial motion vector prediction candidate from the merge list for use in decoding the encoded block of pixels, wherein the spatial motion vector prediction candidate is selected from the merge list using the information that was received identifying a respective spatial motion vector prediction candidate.

10. The method according to claim 9 comprising comparing motion information of the potential spatial motion vector prediction candidate with motion information of at most one other spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates.

11. The method according to claim 9 comprising examining whether the received encoded block of pixels is divided into a first prediction unit and a second prediction unit; and if so, excluding the potential spatial motion vector prediction candidate from the merge list if the prediction unit is the second prediction unit.

12. The method according to claim 9 further comprising determining a maximum number of spatial motion vector prediction candidates to be included in a merge list; and limiting the number of spatial motion vector prediction candidates in the merge list smaller or equal to the maximum number.

13. The method according to claim 12 comprising: examining, if the number of spatial motion vector prediction candidates in the merge list smaller than the maximum number;

if so, examining whether the prediction unit to which the potential spatial motion vector prediction candidate belongs is available for motion prediction;

if so, performing at least one of the following:

for a potential spatial motion vector prediction candidate on a left side of the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

- the received encoded block of pixels is vertically divided into a first prediction unit and a second prediction unit;

- the received encoded block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and if the prediction unit is the second prediction unit, and the potential spatial motion vector prediction candidate has essentially similar motion information than a spatial motion vector prediction candidate above the prediction unit;

for a potential spatial motion vector prediction candidate above the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

- the received encoded block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and the prediction unit is the second prediction unit;

- the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for a potential spatial motion vector prediction candidate, which is on a right side of the potential spatial motion vector prediction candidate above the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

35

for a potential spatial motion vector prediction candidate, which is below the potential spatial motion vector prediction candidate on the left side of the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit; and

for a potential spatial motion vector prediction candidate cornerwise neighbouring the prediction unit, excluding the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

all the other potential spatial motion vector prediction candidates have been included in the merge list;

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit.

14. The method according to claim 9 comprising selecting one motion vector prediction candidate from the merge list to represent a motion vector prediction for the received encoded block of pixels.

15. An apparatus comprising a processor and a memory including computer program code, the memory and the computer program code configured to, with the processor, cause the apparatus to:

receive a block of pixels including a prediction unit;

determine a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

select a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit, where the merge list is constructed based on the motion information of the spatial motion vector prediction candidates and is utilized to identify motion vector prediction candidates of which one spatial motion vector prediction candidate from the merge list is signaled as the motion information for the prediction unit;

determine a subset of spatial motion vector-prediction candidates based on the location of the block associated with the first spatial motion vector prediction candidate;

compare motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates without making a comparison of each possible candidate pair from the set of spatial motion vector prediction candidates, wherein comparing comprises performing an equivalence check or comparing a difference in motion information to a threshold or other similarity metric;

if at least one the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, exclude the first spatial motion vector prediction candidate from the merge list; and

36

cause information identifying the one spatial motion vector prediction candidate from the merge list to be transmitted to a decoder or to be stored.

16. An apparatus comprising a processor and a memory including computer program code, the memory and the computer program code configured to, with the processor, cause the apparatus to:

receive an encoded block of pixels including a prediction unit and information identifying a respective spatial motion vector prediction candidate from a merge list constructed by an encoder;

determine a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

select a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit, where the merge list is constructed based on the motion information of the spatial motion vector prediction candidates;

determine a subset of spatial motion vector prediction candidates based on the location of the block associated with the first spatial motion vector prediction candidate;

compare motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates without making a comparison of each possible candidate pair from the set of spatial motion vector prediction candidates, wherein comparing comprises performing an equivalence check or comparing a difference in motion information to a threshold or other similarity metric;

exclude the first spatial motion vector prediction candidate from the merge list, if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other; and

select a spatial motion vector prediction candidate from the merge list for use in decoding the encoded block of pixels, wherein the spatial motion vector prediction candidate is selected from the merge list using the information that was received identifying a respective spatial motion vector prediction candidate.

17. A non-transitory computer readable medium having stored thereon a computer executable program code for use by an encoder, said program codes comprise instructions for use by an encoder, said program code comprises instructions for:

receiving a block of pixels including a prediction unit; determining a set of spatial motion vector prediction candidates for the block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit, where the merge list is constructed based on the motion information of the spatial motion vector prediction candidates and is utilized to identify motion vector prediction candidates of which one spatial

37

motion vector prediction candidate from the merge list is signaled as the motion information for the prediction unit;

determining a subset of spatial motion vector prediction candidates based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates without making a comparison of each possible candidate pair from the set of spatial motion vector prediction candidates, wherein comparing comprises performing an equivalence check or comparing a difference in motion information to a threshold or other similarity metric;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list; and

causing information identifying the one spatial motion vector prediction candidate from the merge list to be transmitted to a decoder or to be stored.

18. A non-transitory computer readable medium having stored thereon a computer executable program code for use by an encoder, said program codes comprise instructions for use by an encoder, said program code comprises instructions for:

receiving an encoded block of pixels including a prediction unit and information identifying a respective spatial motion vector prediction candidate from a merge list constructed by an encoder;

determining a set of spatial motion vector prediction candidates for the encoded block of pixels; the spatial motion vector prediction candidates being provided with motion information;

selecting a first spatial motion vector prediction candidate from the set of spatial motion vector prediction candidates as a potential spatial motion vector prediction candidate to be included in a merge list for the prediction unit, where the merge list is constructed based on the motion information of the spatial motion vector prediction candidates;

determining a subset of spatial motion vector prediction candidates based on the location of the block associated with the first spatial motion vector prediction candidate;

comparing motion information of the first spatial motion vector prediction candidate with motion information of the spatial motion vector prediction candidate in the determined subset of spatial motion vector prediction candidates without making a comparison of each possible candidate pair from the set of spatial motion vector prediction candidates, wherein comparing comprises performing an equivalence check or comparing a difference in motion information to a threshold or other similarity metric;

if at least one of the comparisons indicates that the motion vector information of the spatial motion vector prediction candidates correspond with each other, excluding the first spatial motion vector prediction candidate from the merge list; and

selecting a spatial motion vector prediction candidate from the merge list for use in decoding the encoded block of pixels, wherein the spatial motion vector

38

prediction candidate is selected from the merge list using the information that was received identifying a respective spatial motion vector prediction candidate.

19. The apparatus according to claim 15 wherein the apparatus is further caused to select spatial motion vector prediction candidates from the set of spatial motion vector prediction candidates as the potential spatial motion vector prediction candidate in a predetermined order.

20. The apparatus according to claim 15, wherein the apparatus is further caused to examine whether the received block of pixels is divided into a first prediction unit and a second prediction unit; and if so, exclude the potential spatial motion vector prediction candidate from the merge list if the prediction unit is the second prediction unit.

21. The apparatus according to claim 15 wherein the apparatus is further caused to examine whether the received block of pixels is divided into a first prediction unit and a second prediction unit; and if so, exclude the potential spatial motion vector prediction candidate from the merge list if the prediction unit is the second prediction unit.

22. The apparatus according to claim 15, wherein the apparatus is further caused to:

determine a maximum number of spatial motion vector prediction candidates to be included in a merge list; and

limit the number of spatial motion vector prediction candidates in the merge list smaller or equal to the maximum number.

23. The apparatus according to claim 22 wherein the apparatus is further caused to:

examine, if the number of spatial motion vector prediction candidates in the merge list smaller than the maximum number;

if so, examine whether the prediction unit to which the potential spatial motion vector prediction candidate belongs is available for motion prediction;

if so, perform at least one of the following:

for a potential spatial motion vector prediction candidate on a left side of the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

the received block of pixels is vertically divided into a first prediction unit and a second prediction unit;

the received block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and if the prediction unit is the second prediction unit, and the potential spatial motion vector prediction candidate has essentially similar motion information than a spatial motion vector prediction candidate above the prediction unit;

for a potential spatial motion vector prediction candidate above the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

the received block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and the prediction unit is the second prediction unit;

the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for a potential spatial motion vector prediction candidate, which is on a right side of the potential spatial motion vector prediction candidate above the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially

39

similar motion information than the spatial motion vector prediction candidate above the prediction unit; for a potential spatial motion vector prediction candidate, which is below the potential spatial motion vector prediction candidate on the left side of the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for a potential spatial motion vector prediction candidate cornerwise neighbouring the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

- all the other potential spatial motion vector prediction candidates have been included in the merge list;
- the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;
- the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit.

24. The apparatus according to claim 15 wherein the apparatus is further caused to include a temporal motion prediction candidate into the merge list.

25. The apparatus according to claim 15 wherein the apparatus is further caused to select one motion vector prediction candidate from the merge list to represent a motion vector prediction for the block of pixels.

26. The apparatus according to claim 16 wherein the apparatus is further caused to compare motion information of the potential spatial motion vector prediction candidate with motion information of at most one other spatial motion vector prediction candidate of the set of spatial motion vector prediction candidates.

27. The apparatus according to claim 16 wherein the apparatus is further caused to examine whether the received encoded block of pixels is divided into a first prediction unit and a second prediction unit; and if so, exclude the potential spatial motion vector prediction candidate from the merge list if the prediction unit is the second prediction unit.

28. The apparatus according to claim 16 wherein the apparatus is further caused to:

- determine a maximum number of spatial motion vector prediction candidates to be included in a merge list; and
- limit the number of spatial motion vector prediction candidates in the merge list smaller or equal to the maximum number.

29. The apparatus according to claim 28 wherein the apparatus is further caused to:

- examine if the number of spatial motion vector prediction candidates in the merge list smaller than the maximum number;

if so, examine whether the prediction unit to which the potential spatial motion vector prediction candidate belongs is available for motion prediction;

if so, perform at least one of the following:

- for a potential spatial motion vector prediction candidate on a left side of the prediction unit, exclude the

40

potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

- the received encoded block of pixels is vertically divided into a first prediction unit and a second prediction unit;

- the received encoded block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and if the prediction unit is the second prediction unit, and the potential spatial motion vector prediction candidate has essentially similar motion information than a spatial motion vector prediction candidate above the prediction unit;

for a potential spatial motion vector prediction candidate above the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

- the received encoded block of pixels is horizontally divided into a first prediction unit and a second prediction unit, and the prediction unit is the second prediction unit;

- the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit;

for a potential spatial motion vector prediction candidate, which is on a right side of the potential spatial motion vector prediction candidate above the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

for a potential spatial motion vector prediction candidate, which is below the potential spatial motion vector prediction candidate on the left side of the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit; and

for a potential spatial motion vector prediction candidate cornerwise neighbouring the prediction unit, exclude the potential spatial motion vector prediction candidate from the merge list if any of the following conditions are fulfilled:

- all the other potential spatial motion vector prediction candidates have been included in the merge list;

- the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate above the prediction unit;

- the potential spatial motion vector prediction candidate has essentially similar motion information than the spatial motion vector prediction candidate on the left side of the prediction unit.

30. The apparatus according to claim 16 wherein the apparatus is further caused to select one motion vector prediction candidate from the merge list to represent a motion vector prediction for the received encoded block of pixels.

(57) **ABSTRACT**

Apparatuses, methods and computer programs are provided for utilizing motion prediction in video coding. A block of pixels of a video representation encoded in a bitstream is read, and a type of the block is determined. If the determining indicates that the block is a block predicted by using two or more reference blocks, a first reference pixel location in a first reference block is determined and a second reference pixel location in a second reference block is determined. The first reference pixel location is used to obtain a first prediction. The first prediction has a second precision, which is higher than the first precision. The second reference pixel location is used to obtain a second prediction, which also has the second precision. The first prediction and the second prediction are combined to obtain a combined prediction; and the precision of the combined prediction is reduced to the first precision.

MOTION PREDICTION IN VIDEO CODING**CROSS REFERENCE TO RELATED APPLICATIONS**

This application is a continuation of U.S. application Ser. No. 16/729,974, filed Dec. 30, 2019, which is a continuation of U.S. application Ser. No. 15/876,495, filed Jan. 22, 2018, which is a continuation of U.S. application Ser. No. 15/490,469, filed Apr. 18, 2017, which is a continuation of U.S. application Ser. No. 15/250,124, filed Aug. 29, 2016, which is a continuation of U.S. application Ser. No. 13/344,893, filed on Jan. 6, 2012, which claims priority to U.S. Provisional Application No. 61/430,694, filed Jan. 7, 2011, the entire contents of which are incorporated herein by reference.

TECHNICAL FIELD

The present invention relates to an apparatus, a method and a computer program for producing and utilizing motion prediction information in video encoding and decoding.

BACKGROUND INFORMATION

A video codec may comprise an encoder which transforms input video into a compressed representation suitable for storage and/or transmission and a decoder that can uncompress the compressed video representation back into a viewable form, or either one of them. The encoder may discard some information in the original video sequence in order to represent the video in a more compact form, for example at a lower bit rate.

Many hybrid video codecs, operating for example according to the International Telecommunication Union's ITU-T H.263 and H.264 coding standards, encode video information in two phases. In the first phase, pixel values in a certain picture area or "block" are predicted. These pixel values can be predicted, for example, by motion compensation mechanisms, which involve finding and indicating an area in one of the previously encoded video frames (or a later coded video frame) that corresponds closely to the block being coded. Additionally, pixel values can be predicted by spatial mechanisms which involve finding and indicating a spatial region relationship, for example by using pixel values around the block to be coded in a specified manner.

Prediction approaches using image information from a previous (or a later) image can also be called as Inter prediction methods, and prediction approaches using image information within the same image can also be called as Intra prediction methods.

The second phase is one of coding the error between the predicted block of pixels and the original block of pixels. This is typically accomplished by transforming the difference in pixel values using a specified transform. This transform may be e.g. a Discrete Cosine Transform (DCT) or a variant thereof. After transforming the difference, the transformed difference may be quantized and entropy encoded.

By varying the fidelity of the quantization process, the encoder can control the balance between the accuracy of the pixel representation, (in other words, the quality of the picture) and the size of the resulting encoded video representation (in other words, the file size or transmission bit rate).

An example of the encoding process is illustrated in FIG.

1.

The decoder reconstructs the output video by applying a prediction mechanism similar to that used by the encoder in order to form a predicted representation of the pixel blocks (using the motion or spatial information created by the encoder and stored in the compressed representation of the image) and prediction error decoding (the inverse operation of the prediction error coding to recover the quantized prediction error signal in the spatial domain).

After applying pixel prediction and error decoding processes the decoder combines the prediction and the prediction error signals (the pixel values) to form the output video frame.

The decoder (and encoder) may also apply additional filtering processes in order to improve the quality of the output video before passing it for display and/or storing as a prediction reference for the forthcoming frames in the video sequence.

An example of the decoding process is illustrated in FIG.

2.

Motion Compensated Prediction (MCP) is a technique used by video compression standards to reduce the size of an encoded bitstream. In MCP, a prediction for a current frame is formed using a previously coded frame(s), where only the difference between original and prediction signals, representative of the current and predicted frames, is encoded and sent to a decoder. A prediction signal, representative of a prediction frame, is formed by first dividing a current frame into blocks, e.g., macroblocks, and searching for a best match in a reference frame for each block. In this way, the motion of a block relative to the reference frame is determined and this motion information is coded into a bitstream as motion vectors. A decoder is able to reconstruct the exact prediction frame by decoding the motion vector data encoded in the bitstream.

An example of a prediction structure is presented in FIG. 8. Boxes indicate pictures, capital letters within boxes indicate coding types, numbers within boxes are picture numbers (in decoding order), and arrows indicate prediction dependencies. In this example I-pictures are intra pictures which do not use any reference pictures and thus can be decoded irrespective of the decoding of other pictures. P-pictures are so called uni-predicted pictures i.e. they refer to one reference picture, and B-pictures are bi-predicted pictures which use two other pictures as reference pictures, or two prediction blocks within one reference picture. In other words, the reference blocks relating to the B-picture may be in the same reference picture (as illustrated with the two arrows from picture P7 to picture B8 in FIG. 8) or in two different reference pictures (as illustrated e.g. with the arrows from picture P2 and from picture B3 to picture B4 in FIG. 8).

It should also be noted here that one picture may include different types of blocks i.e. blocks of a picture may be intra-blocks, uni-predicted blocks, and/or bi-predicted blocks. Motion vectors often relate to blocks wherein for one picture a plurality of motion vectors may exist.

In some systems the uni-predicted pictures are also called as uni-directionally predicted pictures and the bi-predicted pictures are called as bi-directionally predicted pictures.

The motion vectors are not limited to having full-pixel accuracy, but could have fractional-pixel accuracy as well. That is, motion vectors can point to fractional-pixel positions/locations of the reference frame, where the fractional-pixel locations can refer to, for example, locations "in between" image pixels. In order to obtain samples at fractional-pixel locations, interpolation filters may be used in the MCP process. Conventional video coding standards describe

how a decoder can obtain samples at fractional-pixel accuracy by defining an interpolation filter. In MPEG-2, for example, motion vectors can have at most, half-pixel accuracy, where the samples at half-pixel locations are obtained by a simple averaging of neighboring samples at full-pixel locations. The H.264/AVC video coding standard supports motion vectors with up to quarter-pixel accuracy. Furthermore, in the H.264/AVC video coding standard, half-pixel samples are obtained through the use of symmetric and separable 6-tap filters, while quarter-pixel samples are obtained by averaging the nearest half or full-pixel samples.

In typical video codecs, the motion information is indicated by motion vectors associated with each motion compensated image block. Each of these motion vectors represents the displacement of the image block in the picture to be coded (in the encoder) or decoded (at the decoder) and the prediction source block in one of the previously coded or decoded images (or pictures). In order to represent motion vectors efficiently, motion vectors are typically coded differentially with respect to block specific predicted motion vector. In a typical video codec, the predicted motion vectors are created in a predefined way, for example by calculating the median of the encoded or decoded motion vectors of the adjacent blocks.

In typical video codecs the prediction residual after motion compensation is first transformed with a transform kernel (like DCT) and then coded. The reason for this is that often there still exists some correlation among the residual and transform can in many cases help reduce this correlation and provide more efficient coding.

Typical video encoders utilize the Lagrangian cost function to find optimal coding modes, for example the desired macro block mode and associated motion vectors. This type of cost function uses a weighting factor or λ to tie together the exact or estimated image distortion due to lossy coding methods and the exact or estimated amount of information required to represent the pixel values in an image area.

This may be represented by the equation:

$$C = D + \lambda R \quad (1)$$

where C is the Lagrangian cost to be minimised, D is the image distortion (for example, the mean-squared error between the pixel values in original image block and in coded image block) with the mode and motion vectors currently considered, λ is a Lagrangian coefficient and R is the number of bits needed to represent the required data to reconstruct the image block in the decoder (including the amount of data to represent the candidate motion vectors).

Some hybrid video codecs, such as H.264/AVC, utilize bi-directional motion compensated prediction to improve the coding efficiency. In bi-directional prediction, prediction signal of the block may be formed by combining, for example by averaging two motion compensated prediction blocks. This averaging operation may further include either up or down rounding, which may introduce rounding errors.

The accumulation of rounding errors in bi-directional prediction may cause degradation in coding efficiency. This rounding error accumulation may be removed or decreased by signalling whether rounding up or rounding down have been used when the two prediction signals have been combined for each frame. Alternatively the rounding error could be controlled by alternating the usage of the rounding up and rounding down for each frame. For example, rounding up may be used for every other frame and, correspondingly, rounding down may be used for every other frame.

In FIG. 9 an example of averaging two motion compensated prediction blocks using rounding is illustrated. Sample

values of the first prediction reference is input **902** to a first filter **904** in which values of two or more full pixels near the point which the motion vector is referring to are used in the filtering. A rounding offset may be added **906** to the filtered value. The filtered value added with the rounding offset is right shifted **908** x-bits i.e. divided by 2^x to obtain a first prediction signal **P1**. Similar operation is performed to the second prediction reference as is illustrated with blocks **912**, **914**, **916** and **918** to obtain a second prediction signal **P2**. The first prediction signal **P1** and the second prediction signal **P2** are combined e.g. by summing the prediction signals **P1**, **P2**. A rounding offset may be added **920** with the combined signal after which the result is right shifted y-bits i.e. divided by 2^y . The rounding may be upwards, if the rounding offset is positive, or downwards, if the rounding offset is negative. The direction of the rounding may always be the same, or it may alter from time to time, e.g. for each frame. The direction of the rounding may be signaled in the bitstream so that in the decoding process the same rounding direction can be used.

However, these methods increase somewhat the complexity as two separate code branches need to be written for bi-directional averaging. In addition, the motion estimation routines in the encoder may need to be doubled for both cases of rounding and truncation.

SUMMARY

The present invention introduces a method which enables reducing the effect of rounding errors in bi-directional and multi-directional prediction. According to some embodiments of the invention prediction signals are maintained in a higher precision during the prediction calculation and the precision is reduced after the two or more prediction signals have been combined with each other.

In some example embodiments prediction signals are maintained in higher accuracy until the prediction signals have been combined to obtain the bi-directional or multidirectional prediction signal. The accuracy of the bi-directional or multidirectional prediction signal can then be downshifted to an appropriate accuracy for post processing purposes. Then, no rounding direction indicator need not be included in or read from the bitstream.

According to a first aspect of the present invention there is provided a method comprising:

determining a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

determining a type of the block;

if the determining indicates that the block is a block predicted by using two or more reference blocks,

determining a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

using said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

using said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

combining said first prediction and said second prediction to obtain a combined prediction; and

decreasing the precision of said combined prediction to said first precision.

According to a second aspect of the present invention there is provided an apparatus comprising:

a processor; and

5

a memory unit operatively connected to the processor and including:

computer code configured to determine a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

computer code configured to determine a type of the block;

computer code configured to, if the determining indicates that the block is a block predicted by using two or more reference blocks,

determine a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

use said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

combine said first prediction and said second prediction to obtain a combined prediction; and

decrease the precision of said combined prediction to said first precision.

According to a third aspect of the present invention there is provided a computer readable storage medium stored with code thereon for use by an apparatus, which when executed by a processor, causes the apparatus to perform:

determine a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

determine a type of the block;

if the determining indicates that the block is a block predicted by using two or more reference blocks,

determine a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

use said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

combine said first prediction and said second prediction to obtain a combined prediction; and

decrease the precision of said combined prediction to said first precision.

According to a fourth aspect of the present invention there is provided at least one processor and at least one memory, said at least one memory stored with code thereon, which when executed by said at least one processor, causes an apparatus to perform:

determine a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

determine a type of the block;

if the determining indicates that the block is a block predicted by using two or more reference blocks,

determine a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

use said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

6

combine said first prediction and said second prediction to obtain a combined prediction; and

decrease the precision of said combined prediction to said first precision.

According to a fifth aspect of the present invention there is provided an apparatus comprising:

an input to determine a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

a determinator to determine a type of the block; wherein if the determining indicates that the block is a block predicted by using two or more reference blocks, said determinator further to determine a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

a first predictor to use said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

a second predictor to use said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

a combiner to combine said first prediction and said second prediction to obtain a combined prediction; and

a shifter to decrease the precision of said combined prediction to said first precision.

According to a sixth aspect of the present invention there is provided an apparatus comprising:

means for determining a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

means for determining a type of the block;

means for determining a first reference pixel location in a first reference block and a second reference pixel location in a second reference block, if the determining indicates that the block is a block predicted by using two or more reference blocks;

means for using said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

means for using said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

means for combining said first prediction and said second prediction to obtain a combined prediction; and

means for decreasing the precision of said combined prediction to said first precision.

This invention removes the need to signal the rounding offset or use different methods for rounding for different frames. This invention may keep the motion compensated prediction signal of each one of the predictions at highest precision possible after interpolation and perform the rounding to the bit-depth range of the video signal after both prediction signals are added.

DESCRIPTION OF THE DRAWINGS

For better understanding of the present invention, reference will now be made by way of example to the accompanying drawings in which:

FIG. 1 shows schematically an electronic device employing some embodiments of the invention;

FIG. 2 shows schematically a user equipment suitable for employing some embodiments of the invention;

7

FIG. 3 further shows schematically electronic devices employing embodiments of the invention connected using wireless and wired network connections;

FIG. 4a shows schematically an embodiment of the invention as incorporated within an encoder;

FIG. 4b shows schematically an embodiment of an inter predictor according to some embodiments of the invention;

FIG. 5 shows a flow diagram showing the operation of an embodiment of the invention with respect to the encoder as shown in FIG. 4a;

FIG. 6 shows a schematic diagram of a decoder according to some embodiments of the invention;

FIG. 7 shows a flow diagram of showing the operation of an embodiment of the invention with respect to the decoder shown in FIG. 6;

FIG. 8 illustrates an example of a prediction structure in a video sequence;

FIG. 9 depicts an example of a bit stream of an image;

FIG. 10 depicts an example of bi-directional prediction using rounding;

FIG. 11 depicts an example of bi-directional prediction according to an example embodiment of the present invention; and

FIG. 12 illustrates an example of some possible prediction directions for a motion vector.

DETAILED DESCRIPTION OF SOME EXAMPLE EMBODIMENTS

The following describes in further detail suitable apparatus and possible mechanisms for the provision of reducing information to be transmitted in video coding systems and more optimal codeword mappings in some embodiments. In this regard reference is first made to FIG. 1 which shows a schematic block diagram of an exemplary apparatus or electronic device 50, which may incorporate a codec according to an embodiment of the invention.

The electronic device 50 may for example be a mobile terminal or user equipment of a wireless communication system. However, it would be appreciated that embodiments of the invention may be implemented within any electronic device or apparatus which may require encoding and decoding or encoding or decoding video images.

The apparatus 50 may comprise a housing 30 for incorporating and protecting the device. The apparatus 50 further may comprise a display 32 in the form of a liquid crystal display. In other embodiments of the invention the display may be any suitable display technology suitable to display an image or video. The apparatus 50 may further comprise a keypad 34. In other embodiments of the invention any suitable data or user interface mechanism may be employed. For example the user interface may be implemented as a virtual keyboard or data entry system as part of a touch-sensitive display. The apparatus may comprise a microphone 36 or any suitable audio input which may be a digital or analogue signal input. The apparatus 50 may further comprise an audio output device which in embodiments of the invention may be any one of: an earpiece 38, speaker, or an analogue audio or digital audio output connection. The apparatus 50 may also comprise a battery 40 (or in other embodiments of the invention the device may be powered by any suitable mobile energy device such as solar cell, fuel cell or clockwork generator). The apparatus may further comprise an infrared port 42 for short range line of sight communication to other devices. In other embodiments the apparatus 50 may further comprise any suitable short range

8

communication solution such as for example a Bluetooth wireless connection or a USB/firewire wired connection.

The apparatus 50 may comprise a controller 56 or processor for controlling the apparatus 50. The controller 56 may be connected to memory 58 which in embodiments of the invention may store both data in the form of image and audio data and/or may also store instructions for implementation on the controller 56. The controller 56 may further be connected to codec circuitry 54 suitable for carrying out coding and decoding of audio and/or video data or assisting in coding and decoding carried out by the controller 56.

The apparatus 50 may further comprise a card reader 48 and a smart card 46, for example a UICC and UICC reader for providing user information and being suitable for providing authentication information for authentication and authorization of the user at a network.

The apparatus 50 may comprise radio interface circuitry 52 connected to the controller and suitable for generating wireless communication signals for example for communication with a cellular communications network, a wireless communications system or a wireless local area network. The apparatus 50 may further comprise an antenna 44 connected to the radio interface circuitry 52 for transmitting radio frequency signals generated at the radio interface circuitry 52 to other apparatus(es) and for receiving radio frequency signals from other apparatus(es).

In some embodiments of the invention, the apparatus 50 comprises a camera capable of recording or detecting individual frames which are then passed to the codec 54 or controller for processing. In some embodiments of the invention, the apparatus may receive the video image data for processing from another device prior to transmission and/or storage. In some embodiments of the invention, the apparatus 50 may receive either wirelessly or by a wired connection the image for coding/decoding.

With respect to FIG. 3, an example of a system within which embodiments of the present invention can be utilized is shown. The system 10 comprises multiple communication devices which can communicate through one or more networks. The system 10 may comprise any combination of wired or wireless networks including, but not limited to a wireless cellular telephone network (such as a GSM, UMTS, CDMA network etc), a wireless local area network (WLAN) such as defined by any of the IEEE 802.x standards, a Bluetooth personal area network, an Ethernet local area network, a token ring local area network, a wide area network, and the Internet.

The system 10 may include both wired and wireless communication devices or apparatus 50 suitable for implementing embodiments of the invention.

For example, the system shown in FIG. 3 shows a mobile telephone network 11 and a representation of the internet 28. Connectivity to the internet 28 may include, but is not limited to, long range wireless connections, short range wireless connections, and various wired connections including, but not limited to, telephone lines, cable lines, power lines, and similar communication pathways.

The example communication devices shown in the system 10 may include, but are not limited to, an electronic device or apparatus 50, a combination of a personal digital assistant (PDA) and a mobile telephone 14, a PDA 16, an integrated messaging device (IMD) 18, a desktop computer 20, a notebook computer 22. The apparatus 50 may be stationary or mobile when carried by an individual who is moving. The apparatus 50 may also be located in a mode of transport including, but not limited to, a car, a truck, a taxi, a bus, a

train, a boat, an airplane, a bicycle, a motorcycle or any similar suitable mode of transport.

Some or further apparatus may send and receive calls and messages and communicate with service providers through a wireless connection **25** to a base station **24**. The base station **24** may be connected to a network server **26** that allows communication between the mobile telephone network **11** and the internet **28**. The system may include additional communication devices and communication devices of various types.

The communication devices may communicate using various transmission technologies including, but not limited to, code division multiple access (CDMA), global systems for mobile communications (GSM), universal mobile telecommunications system (UMTS), time divisional multiple access (TDMA), frequency division multiple access (FDMA), transmission control protocol-internet protocol (TCP-IP), short messaging service (SMS), multimedia messaging service (MMS), email, instant messaging service (IMS), Bluetooth, IEEE 802.11 and any similar wireless communication technology. A communications device involved in implementing various embodiments of the present invention may communicate using various media including, but not limited to, radio, infrared, laser, cable connections, and any suitable connection.

Various embodiments can extend conventional two-stage sub-pixel interpolation algorithms, such as the algorithm used in the H.264/AVC video coding standard, without the need to increase the complexity of the decoder. It should be noted here that FIG. **11** illustrates only some full pixel values which are the nearest neighbors to the example block of pixels but in the interpolation it may also be possible to use full pixel values located farther from the block under consideration. Furthermore, the present invention is not only limited to implementations using one-dimensional interpolation but the fractional pixel samples can also be obtained using more complex interpolation or filtering.

It should be noted that various embodiments can be implemented by and/or in conjunction with other video coding standards besides the H.264/AVC video coding standard.

With respect to FIG. **4a**, a block diagram of a video encoder suitable for carrying out embodiments of the invention is shown. Furthermore, with respect to FIG. **5**, the operation of the encoder exemplifying embodiments of the invention specifically with respect to the utilization of higher accuracy calculation of prediction signals is shown as a flow diagram.

FIG. **4a** shows the encoder as comprising a pixel predictor **302**, prediction error encoder **303** and prediction error decoder **304**. FIG. **4a** also shows an embodiment of the pixel predictor **302** as comprising an inter-predictor **306**, an intra-predictor **308**, a mode selector **310**, a filter **316**, and a reference frame memory **318**. The mode selector **310** comprises a block processor **381** and a cost evaluator **382**. FIG. **4b** also depicts an embodiment of the inter-predictor **306** which comprises a block selector **360** and a motion vector definer **361**, which may be implemented e.g. in a prediction processor **362**. The inter-predictor **306** may also have access to a parameter memory **404**. The mode selector **310** may also comprise a quantizer **384**.

The pixel predictor **302** receives the image **300** to be encoded at both the inter-predictor **306** (which determines the difference between the image and a motion compensated reference frame **318**) and the intra-predictor **308** (which determines a prediction for an image block based only on the already processed parts of current frame or picture). The

output of both the inter-predictor and the intra-predictor are passed to the mode selector **310**. The intra-predictor **308** may have more than one intra-prediction modes. Hence, each mode may perform the intra-prediction and provide the predicted signal to the mode selector **310**. The mode selector **310** also receives a copy of the image **300**.

The block processor **381** determines which encoding mode to use to encode the current block. If the block processor **381** decides to use an inter-prediction mode it will pass the output of the inter-predictor **306** to the output of the mode selector **310**. If the block processor **381** decides to use an intra-prediction mode it will pass the output of one of the intra-predictor modes to the output of the mode selector **310**.

According to some example embodiments the pixel predictor **302** operates as follows. The inter predictor **306** and the intra prediction modes **308** perform the prediction of the current block to obtain predicted pixel values of the current block. The inter predictor **306** and the intra prediction modes **308** may provide the predicted pixel values of the current block to the block processor **381** for analyzing which prediction to select. In addition to the predicted values of the current block, the block processor **381** may, in some embodiments, receive an indication of a directional intra prediction mode from the intra prediction modes.

The block processor **381** examines whether to select the inter prediction mode or the intra prediction mode. The block processor **381** may use cost functions such as the equation (1) or some other methods to analyze which encoding method gives the most efficient result with respect to a certain criterion or criteria. The selected criteria may include coding efficiency, processing costs and/or some other criteria. The block processor **381** may examine the prediction for each directionality i.e. for each intra prediction mode and inter prediction mode and calculate the cost value for each intra prediction mode and inter prediction mode, or the block processor **381** may examine only a subset of all available prediction modes in the selection of the prediction mode.

In some embodiments the inter predictor **306** operates as follows. The block selector **360** receives a current block to be encoded (block **504** in FIG. **5**) and examines whether a previously encoded image contains a block which may be used as a reference to the current block (block **505**). If such a block is found from the reference frame memory **318**, the motion estimator **365** may determine whether the current block could be predicted by using one or two (or more) reference blocks i.e. whether the current block could be a uni-predicted block or a bi-predicted block (block **506**). If the motion estimator **365** has determined to use uni-prediction, the motion estimator **365** may indicate the reference block to the motion vector definer **361**. If the motion estimator **365** has selected to use bi-prediction, the motion estimator **365** may indicate both reference blocks, or if more than two reference blocks have been selected, all the selected reference blocks to the motion vector definer **361**. The motion vector definer **361** utilizes the reference block information and defines a motion vector (block **507**) to indicate the correspondence between pixels of the current block and the reference block(s).

In some embodiments the inter predictor **306** calculates a cost value for both one-directional and bi-directional prediction and may then select which kind of prediction to use with the current block.

In some embodiments the motion vector may point to a full pixel sample or to a fraction pixel sample i.e. to a half pixel, to a quarter pixel or to a one-eighth pixel. The motion vector definer **361** may examine the type of the current block

11

to determine whether the block is a bi-predicted block or another kind of a block (block **508**). The type may be determined by the block type indication **366** which may be provided by the block selector **360** or another element of the encoder. If the type of the block is a bi-predicted block, two (or more) motion vectors are defined by the motion vector definer **361** (block **509**). Otherwise, if the block is a uni-predicted block, one motion vector shall be defined (block **510**).

It is also possible that the type of the block is determined before the motion vector is calculated.

The motion vector definer **361** provides motion vector information to the block processor **381** which uses this information to obtain the prediction signal.

When the cost has been calculated with respect to intra prediction mode and possibly with respect to the inter prediction mode(s), the block processor **381** selects one intra prediction mode or the inter prediction mode for encoding the current block.

When the inter prediction mode was selected, the predicted pixel values or predicted pixel values quantized by the optional quantizer **384** are provided as the output of the mode selector.

The output of the mode selector is passed to a first summing device **321**. The first summing device may subtract the pixel predictor **302** output from the image **300** to produce a first prediction error signal **320** which is input to the prediction error encoder **303**.

The pixel predictor **302** further receives from a preliminary reconstructor **339** the combination of the prediction representation of the image block **312** and the output **338** of the prediction error decoder **304**. The preliminary reconstructed image **314** may be passed to the intra-predictor **308** and to a filter **316**. The filter **316** receiving the preliminary representation may filter the preliminary representation and output a final reconstructed image **340** which may be saved in a reference frame memory **318**. The reference frame memory **318** may be connected to the inter-predictor **306** to be used as the reference image against which the future image **300** is compared in inter-prediction operations.

The operation of the pixel predictor **302** may be configured to carry out any known pixel prediction algorithm known in the art.

The pixel predictor **302** may also comprise a filter **385** to filter the predicted values before outputting them from the pixel predictor **302**.

The operation of the prediction error encoder **303** and prediction error decoder **304** will be described hereafter in further detail. In the following examples the encoder generates images in terms of 16×16 pixel macroblocks which go to form the full image or picture. Thus, for the following examples the pixel predictor **302** outputs a series of predicted macroblocks of size 16×16 pixels and the first summing device **321** outputs a series of 16×16 pixel residual data macroblocks which may represent the difference between a first macro-block in the image **300** against a predicted macro-block (output of pixel predictor **302**). It would be appreciated that other size macro blocks may be used.

The prediction error encoder **303** comprises a transform block **342** and a quantizer **344**. The transform block **342** transforms the first prediction error signal **320** to a transform domain. The transform is, for example, the DCT transform. The quantizer **344** quantizes the transform domain signal, e.g. the DCT coefficients, to form quantized coefficients.

The entropy encoder **330** receives the output of the prediction error encoder and may perform a suitable entropy

12

encoding/variable length encoding on the signal to provide error detection and correction capability. Any suitable entropy encoding algorithm may be employed.

The prediction error decoder **304** receives the output from the prediction error encoder **303** and performs the opposite processes of the prediction error encoder **303** to produce a decoded prediction error signal **338** which when combined with the prediction representation of the image block **312** at the second summing device **339** produces the preliminary reconstructed image **314**. The prediction error decoder may be considered to comprise a dequantizer **346**, which dequantizes the quantized coefficient values, e.g. DCT coefficients, to reconstruct the transform signal and an inverse transformation block **348**, which performs the inverse transformation to the reconstructed transform signal wherein the output of the inverse transformation block **348** contains reconstructed block(s). The prediction error decoder may also comprise a macroblock filter (not shown) which may filter the reconstructed macroblock according to further decoded information and filter parameters.

The operation and implementation of the mode selector **310** is shown in further detail with respect to FIG. 5. On the basis of the prediction signals from the output of the inter-predictor **306**, the output of the intra-predictor **308** and/or the image signal **300** the block processor **381** determines which encoding mode to use to encode the current image block. This selection is depicted as the block **500** in FIG. 5. The block processor **381** may calculate a rate-distortion cost (RD) value or another cost value for the prediction signals which are input to the mode selector **310** and select such an encoding mode **503**, **504** for which the determined cost is the smallest.

The mode selector **310** provides an indication of the encoding mode of the current block (**501**). The indication may be encoded and inserted to a bit stream or stored into a memory together with the image information.

If the intra-prediction mode is selected, the block is predicted by an intra-prediction method (**503**). Respectively, if the inter-prediction mode is selected, the block is predicted by an inter-prediction method (**504-510**).

An example of the operation of the mode selector when the inter-prediction mode is selected and the type of the block is a bi-predicted block, is illustrated as a block diagram in FIG. 11. Motion vector information provided by the motion vector definer **361** contains indication of a first reference block and a second reference block. In multi-prediction applications the motion vector information may contain indication of more than two reference blocks. The block processor **381** uses the motion vector information to determine which block is used as a first reference block for the current block and which block is used as a second reference block for the current block. The block processor **381** then uses some pixel values of the first reference block to obtain first prediction values and some pixel values of the second reference block to obtain second prediction values. For example, if a first motion vector points to a fraction of a pixel (a subpixel) illustrated by the square b in the example of FIG. 12, the block processor **381** may use pixel values of several full pixels on the same row, for example, than said fraction of the pixel to obtain a reference pixel value. The block processor **381** may use e.g. a P-tap filter such as a six-tap filter in which P pixel values of the reference block are used to calculate the prediction value. In the example of FIG. 12 these pixel values could be pixels E, F, G, H, I and J. The taps of the filter may be e.g. integer values. An example of such a six-tap filter is [1-5 20 20-5 1]/32. Hence, the filter **1102** would receive **1101** the pixel values of

13

pixels E, F, G, H, I and J and filter these values by the equation $P1=(E_1-5*F_1+20*G_1+20*H_1-5*I_1+J_1)$, in which E_1 is the value of the pixel E in the first reference block, F_1 is the value of the pixel F in the first reference block, G_1 is the value of the pixel G in the first reference block, H_1 is the value of the pixel H in the first reference block, I_1 is the value of the pixel I in the first reference block, and J_1 is the value of the pixel J in the first reference block. In the first rounding offset insertion block **1103** a first rounding offset may be added to the value $P1$ i.e. $P1+\text{rounding offset}$. Then, the sum may be shifted by the first shifting block **1104** to the right so that the precision of the sum becomes M bits. The precision M is higher than the precision of the expected prediction value. For example, pixel values and the prediction values may be represented by N bits wherein $M>N$. In some example implementations N is 8 bits and M is 16 bits but it is obvious that also other bit lengths can be used with the present invention.

The second prediction can be obtained similarly by the second filter **1106**, which receives **1105** some pixel values of the second reference block. These pixel values are determined on the basis of the second motion vector. The second motion vector may point to the same pixel (or a fraction of the pixel) in the second reference block to which the first motion vector points in the first reference block (using the example above that pixel is the subpixel b) or to another full pixel or a subpixel in the second reference block. The second filter **1106** uses similar filter than the first filter **1102** and outputs the second filtering result $P2$. According to the example above the filter is a six-tap filter $[1 \ -5 \ 20 \ 20 \ -5 \ 1]/32$, wherein $P2=(E_2-5*F_2+20*G_2+20*H_2-5*I_2+J_2)$, in which E_2 is the value of the pixel E in the second reference block, F_2 is the value of the pixel F in the second reference block, G_2 is the value of the pixel G in the second reference block, H_2 is the value of the pixel H in the second reference block, I_2 is the value of the pixel I in the second reference block, and J_2 is the value of the pixel J in the second reference block. In the second rounding offset insertion block **1107** the first rounding offset may be added to the value $P2$ i.e. $P2+\text{rounding offset}$. Then, the sum may be shifted by the second shifting block **1108** to the right so that the precision of the sum becomes M bits.

In the combining block **1109** the two prediction values $P1$, $P2$ are combined e.g. by summing and the combined value is added with a second rounding value in the third rounding value insertion block **1110**. The result is converted to a smaller precision e.g. by shifting bits of the result to the right y times in the third shifting block **1111**. This corresponds with dividing the result by 2^y . After the conversion the precision of the prediction signal corresponds with the precision of the input pixel values. However, the intermediate results are at a higher precision, wherein possible rounding errors have a smaller effect to the prediction signal compared to existing methods such as the method illustrated in FIG. 10.

In an alternative embodiment the rounding offset is not added separately to the results of the first **1102** and the second filter **1106** but after combining the results in the combining block **1110**. In this case the value of the rounding offset is twice the value of the first rounding offset because in the embodiment of FIG. 11 the first rounding offset is actually added twice, once to $P1$ and once to $P2$.

In some embodiments also the first shifting block **1105** and the second shifting block **1109** are not needed when the precision of registers which store the filtering results is sufficient without reducing the precision of the filtering results. In that case the third shifting block may need to shift

14

the prediction result more than y bits to the right so that the right shifted value P has the same prediction than the input pixel values, for example 8 bits.

In some other example embodiments may partly differ from the above. For example, if a motion vector of one of the prediction directions point to an integer sample, the bit-depth of prediction samples with integer accuracy may be increased by shifting the samples to the left so that the filtering can be performed with values having the same precision.

Samples of each one of the prediction directions could be rounded at an intermediate step to a bit-depth that is still larger than the input bit-depth to make sure all the intermediate values fit to registers of certain length, e.g. 16-bit registers. For example, let's consider the same example above but using filter taps: {3, -17, 78, 78, -17, 3}. Then $P1$ and $P2$ are obtained as:

$$P1=(3*E_1-17*F_1+78*G_1+78*H_1-17*I_1+3*J_1)>>1$$

$$P2=(3*E_2-17*F_2+78*G_2+78*H_2-17*I_2+3*J_2)>>1$$

The bi-directional prediction signal may then be obtained using:

$$P=(P1+P2+32)>>6.$$

When a motion vector points between two full pixels i.e. to a fraction of the pixel, the value for that the reference pixel value may be obtained in several ways. Some possibilities were disclosed above but in the following some further non-limiting examples shall be provided with reference to FIG. 12.

If a motion vector points to the block labeled j the corresponding reference pixel value could be obtained by using full pixel values on the same diagonal than j, or by a two-phase process in which e.g. pixel values of rows around the block j are used to calculate a set of intermediate results and then these intermediate results could be filtered to obtain the reference pixel value. In an example embodiment the full pixel values A and B could be used to calculate a first intermediate result to represent a fraction pixel value aa, full pixel values C and D could be used to calculate a second intermediate result to represent a fraction pixel value bb, and full pixel values E to J could be used to calculate a third intermediate result to represent a fraction pixel value b. Similarly, fourth, fifth and sixth intermediate values to represent fraction pixel values s, gg, hh could be calculated on the basis of full pixel values K to Q; R, S; and T, U. These intermediate results could then be filtered by a six-tap filter, for example.

The prediction signal P obtained by the above described operations need not be provided to a decoder but the encoder uses this information to obtain predicted blocks and prediction error. The prediction error may be provided to the decoder so that the decoder can use corresponding operations to obtain the predicted blocks by prediction and correct the prediction results on the basis of the prediction error. The encoder may also provide motion vector information to the decoder.

In an example embodiment, as is depicted in FIG. 9, the bit stream of an image comprises an indication of the beginning of an image **910**, image information of each block of the image **920**, and indication of the end of the image **930**. The image information of each block of the image **920** may include a block type indicator **932**, and motion vector information **933**. It is obvious that the bit stream may also comprise other information. Further, this is only a simplified

15

image of the bit stream and in practical implementations the contents of the bit stream may be different from what is depicted in FIG. 9.

The bit stream may further be encoded by the entropy encoder 330.

Although the embodiments above have been described with respect to the size of the macroblock being 16×16 pixels, it would be appreciated that the methods and apparatus described may be configured to handle macroblocks of different pixel sizes.

In the following the operation of an example embodiment of the decoder 600 is depicted in more detail with reference to FIG. 6.

At the decoder side similar operations are performed to reconstruct the image blocks. FIG. 6 shows a block diagram of a video decoder suitable for employing embodiments of the invention and FIG. 7 shows a flow diagram of an example of a method in the video decoder. The decoder shows an entropy decoder 600 which performs an entropy decoding on the received signal. The entropy decoder thus performs the inverse operation to the entropy encoder 330 of the encoder described above. The entropy decoder 600 outputs the results of the entropy decoding to a prediction error decoder 602 and a pixel predictor 604.

The pixel predictor 604 receives the output of the entropy decoder 600. The output of the entropy decoder 600 may include an indication on the prediction mode used in encoding the current block. A predictor selector 614 within the pixel predictor 604 determines that an intra-prediction, an inter-prediction, or interpolation operation is to be carried out. The predictor selector may furthermore output a predicted representation of an image block 616 to a first combiner 613. The predicted representation of the image block 616 is used in conjunction with the reconstructed prediction error signal 612 to generate a preliminary reconstructed image 618. The preliminary reconstructed image 618 may be used in the predictor 614 or may be passed to a filter 620. The filter 620 applies a filtering which outputs a final reconstructed signal 622. The final reconstructed signal 622 may be stored in a reference frame memory 624, the reference frame memory 624 further being connected to the predictor 614 for prediction operations.

The prediction error decoder 602 receives the output of the entropy decoder 600. A dequantizer 692 of the prediction error decoder 602 may dequantize the output of the entropy decoder 600 and the inverse transform block 693 may perform an inverse transform operation to the dequantized signal output by the dequantizer 692. The output of the entropy decoder 600 may also indicate that prediction error signal is not to be applied and in this case the prediction error decoder produces an all zero output signal.

The decoder selects the 16×16 pixel residual macroblock to reconstruct. The selection of the 16×16 pixel residual macroblock to be reconstructed is shown in step 700.

The decoder receives information on the encoding mode used when the current block has been encoded. The indication is decoded, when necessary, and provided to the reconstruction processor 691 of the prediction selector 614. The reconstruction processor 691 examines the indication (block 701 in FIG. 7) and selects one of the intra-prediction modes (block 703), if the indication indicates that the block has been encoded using intra-prediction, or an inter-prediction mode (blocks 704-711), if the indication indicates that the block has been encoded using inter-prediction.

If the current block has been encoded using inter-prediction, the pixel predictor 604 may operate as follows. The pixel predictor 604 receives motion vector information

16

(block 704). The pixel predictor 604 also receives (block 705) block type information and examines whether the block is a bi-predicted block or not (block 706). If the block type is a bi-predicted block, the pixel predictor 604 examines the motion vector information to determine which reference frames and reference block in the reference frames have been used in the construction of the motion vector information. The reconstruction processor 691 calculates the motion vectors (709) and uses the value of the (fraction of the) pixel of the reference blocks to which the motion vectors point to obtain a motion compensated prediction (710) and combines the prediction error with the value to obtain a reconstructed value of a pixel of the current block (block 711).

If the block type is a uni-predicted block, the pixel predictor 604 examines the motion vector information to determine which reference frame and reference block in the reference frame has been used in the construction of the motion vector information. The reconstruction processor 691 calculates the motion vector (707) and uses the value of the (fraction of the) pixel of the reference block to which the motion vector points to obtain a motion compensated prediction (708) and combines the prediction error with the value to obtain a reconstructed value of a pixel of the current block (block 711).

When the motion vector does not point to a full pixel sample in the reference block, the reconstruction processor 691 calculates using e.g. a one-directional interpolation or P-tap filtering (e.g. six-tap filtering) to obtain the values of the fractional pixels. Basically, the operations may be performed in the same way than in the encoder i.e. maintaining the higher accuracy values during the filtering until in the final rounding operation the accuracy may be decreased to the accuracy of the input pixels. Therefore, the effect of possible rounding errors may not be so large to the predicted values than in known methods.

The above described procedures may be repeated to each pixel of the current block to obtain all reconstructed pixel values for the current block.

In some embodiments the reconstruction processor 691 uses the interpolator 694 to perform the calculation of the fractional pixel values.

In some embodiments the reconstruction processor 691 provides the fractional pixel values to the predictor 695 which combines the fractional pixel values with prediction error to obtain the reconstructed values of the pixels of the current block.

In some embodiments the interpolation may also be performed by using full pixel values, half pixel values, and/or quarter pixel values which may have been stored into a reference frame memory. For example, the encoder or the decoder may comprise a reference frame memory in which the full pixel samples, half pixel values and quarter pixel values can be stored.

Furthermore, in some embodiments the type of the block may also be a multi-predicted block wherein the prediction of a block may be based on more than two reference blocks.

The embodiments of the invention described above describe the codec in terms of separate encoder and decoder apparatus in order to assist the understanding of the processes involved. However, it would be appreciated that the apparatus, structures and operations may be implemented as a single encoder-decoder apparatus/structure/operation. Furthermore in some embodiments of the invention the coder and decoder may share some or all common elements.

Although the above examples describe embodiments of the invention operating within a codec within an electronic device, it would be appreciated that the invention as

described below may be implemented as part of any video codec. Thus, for example, embodiments of the invention may be implemented in a video codec which may implement video coding over fixed or wired communication paths.

Thus, user equipment may comprise a video codec such as those described in embodiments of the invention above.

It shall be appreciated that the term user equipment is intended to cover any suitable type of wireless user equipment, such as mobile telephones, portable data processing devices or portable web browsers.

Furthermore elements of a public land mobile network (PLMN) may also comprise video codecs as described above.

In general, the various embodiments of the invention may be implemented in hardware or special purpose circuits, software, logic or any combination thereof. For example, some aspects may be implemented in hardware, while other aspects may be implemented in firmware or software which may be executed by a controller, microprocessor or other computing device, although the invention is not limited thereto. While various aspects of the invention may be illustrated and described as block diagrams, flow charts, or using some other pictorial representation, it is well understood that these blocks, apparatus, systems, techniques or methods described herein may be implemented in, as non-limiting examples, hardware, software, firmware, special purpose circuits or logic, general purpose hardware or controller or other computing devices, or some combination thereof.

The embodiments of this invention may be implemented by computer software executable by a data processor of the mobile device, such as in the processor entity, or by hardware, or by a combination of software and hardware. Further in this regard it should be noted that any blocks of the logic flow as in the Figures may represent program steps, or interconnected logic circuits, blocks and functions, or a combination of program steps and logic circuits, blocks and functions. The software may be stored on such physical media as memory chips, or memory blocks implemented within the processor, magnetic media such as hard disk or floppy disks, and optical media such as for example DVD and the data variants thereof, CD.

The memory may be of any type suitable to the local technical environment and may be implemented using any suitable data storage technology, such as semiconductor-based memory devices, magnetic memory devices and systems, optical memory devices and systems, fixed memory and removable memory. The data processors may be of any type suitable to the local technical environment, and may include one or more of general purpose computers, special purpose computers, microprocessors, digital signal processors (DSPs) and processors based on multi-core processor architecture, as non-limiting examples.

Embodiments of the inventions may be practiced in various components such as integrated circuit modules. The design of integrated circuits is by and large a highly automated process. Complex and powerful software tools are available for converting a logic level design into a semiconductor circuit design ready to be etched and formed on a semiconductor substrate.

Programs, such as those provided by Synopsys, Inc. of Mountain View, Calif. and Cadence Design, of San Jose, Calif. automatically route conductors and locate components on a semiconductor chip using well established rules of design as well as libraries of pre-stored design modules. Once the design for a semiconductor circuit has been completed, the resultant design, in a standardized electronic

format (e.g., Opus, GDSII, or the like) may be transmitted to a semiconductor fabrication facility or "fab" for fabrication.

The foregoing description has provided by way of exemplary and non-limiting examples a full and informative description of the exemplary embodiment of this invention. However, various modifications and adaptations may become apparent to those skilled in the relevant arts in view of the foregoing description, when read in conjunction with the accompanying drawings and the appended claims. However, all such and similar modifications of the teachings of this invention will still fall within the scope of this invention.

A method according to a first embodiment comprises:

determining a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

determining a type of the block;

if the determining indicates that the block is a block predicted by using two or more reference blocks,

determining a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

using said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

using said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

combining said first prediction and said second prediction to obtain a combined prediction; and

decreasing the precision of said combined prediction to said first precision.

In some methods according to the first embodiment a first rounding offset is inserted to said first prediction and said second prediction.

In some methods according to the first embodiment the precision of said first prediction and said second prediction is reduced to an intermediate prediction after adding said first rounding offset, said intermediate prediction being higher than said first precision.

In some methods according to the first embodiment a second rounding offset is inserted to the combined prediction before said decreasing.

In some methods according to the first embodiment said type of the block is a bi-directional block.

In some methods according to the first embodiment said type of the block is a multidirectional block.

In some methods according to the first embodiment the first rounding offset is 2^y , and said decreasing comprises right shifting the combined prediction $y+1$ bits.

In some methods according to the first embodiment the first precision is 8 bits.

In some methods according to the first embodiment the value of y is 5.

In some methods according to the first embodiment said first prediction and said second prediction are obtained by filtering pixel values of said reference blocks.

In some methods according to the first embodiment the filtering is performed by a P-tap filter.

An apparatus according to a second embodiment comprises:

a processor; and

a memory unit operatively connected to the processor and including:

computer code configured to determine a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

computer code configured to determine a type of the block;

computer code configured to, if the determining indicates that the block is a block predicted by using two or more reference blocks,

determine a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

use said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

combine said first prediction and said second prediction to obtain a combined prediction; and

decrease the precision of said combined prediction to said first precision.

In some apparatuses according to the second embodiment the computer code is further configured to insert a first rounding offset to said first prediction and said second prediction.

In some apparatuses according to the second embodiment the computer code is further configured to reduce the precision of said first prediction and said second prediction to an intermediate prediction after adding said first rounding offset, said intermediate prediction being higher than said first precision.

In some apparatuses according to the second embodiment the computer code is further configured to insert a second rounding offset to the combined prediction before said decreasing.

In some apparatuses according to the second embodiment said type of the block is a bi-directional block.

In some apparatuses according to the second embodiment said type of the block is a multidirectional block.

In some apparatuses according to the second embodiment the first rounding offset is 2^y , and said decreasing comprises right shifting the combined prediction $y+1$ bits.

In some apparatuses according to the second embodiment the first precision is 8 bits.

In some apparatuses according to the second embodiment the value of y is 5.

In some apparatuses according to the second embodiment the computer code is further configured to obtain said first prediction and said second prediction by filtering pixel values of said reference blocks.

In some apparatuses according to the second embodiment said filtering comprises a P-tap filter.

According to a third embodiment there is provided a computer readable storage medium stored with code thereon for use by an apparatus, which when executed by a processor, causes the apparatus to:

determine a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

determine a type of the block;

if the determining indicates that the block is a block predicted by using two or more reference blocks, determine a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

use said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

combine said first prediction and said second prediction to obtain a combined prediction; and

decrease the precision of said combined prediction to said first precision.

According to a fourth embodiment there is provided at least one processor and at least one memory, said at least one memory stored with code thereon, which when executed by said at least one processor, causes an apparatus to perform:

determine a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

determine a type of the block;

if the determining indicates that the block is a block predicted by using two or more reference blocks,

determine a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

use said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

combine said first prediction and said second prediction to obtain a combined prediction; and

decrease the precision of said combined prediction to said first precision.

According to some example embodiments the apparatus is an encoder.

According to some example embodiments the apparatus is a decoder.

An apparatus according to a fifth embodiment comprises: an input to determine a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

a determinator to determine a type of the block; wherein if the determining indicates that the block is a block predicted by using two or more reference blocks, said determinator further to determine a first reference pixel location in a first reference block and a second reference pixel location in a second reference block;

a first predictor to use said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

a second predictor to use said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

a combiner to combine said first prediction and said second prediction to obtain a combined prediction; and

a shifter to decrease the precision of said combined prediction to said first precision.

An apparatus according to a sixth embodiment comprises: means for determining a block of pixels of a video representation encoded in a bitstream, values of said pixels having a first precision;

means for determining a type of the block;

means for determining a first reference pixel location in a first reference block and a second reference pixel location in a second reference block, if the determining indicates that the block is a block predicted by using two or more reference blocks;

21

means for using said first reference pixel location to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

means for using said second reference pixel location to obtain a second prediction, said second prediction having the second precision, which is higher than said first precision;

means for combining said first prediction and said second prediction to obtain a combined prediction; and

means for decreasing the precision of said combined prediction to said first precision.

What is claimed is:

1. A method for encoding a block of pixels, the method comprising:

determining, for a current block, a first reference block based on a first motion vector and a second reference block based on a second motion vector, wherein the pixels of the current block, the first reference block, and the second reference block have values with a first precision;

using said first reference block to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

using said second reference block to obtain a second prediction, said second prediction having the second precision;

obtaining a combined prediction based at least partly upon said first prediction and said second prediction;

decreasing a precision of said combined prediction by shifting bits of the combined prediction to the right; and encoding residual data in a bitstream, wherein the residual data is determined based upon a difference between the combined prediction and the block of pixels.

2. The method according to claim 1, wherein in an instance in which said first motion vector points to a subpixel, said first prediction is obtained by interpolation using pixel values of said first reference block.

3. The method according to claim 2, wherein said first prediction is obtained by interpolation using values of said first reference block by:

right shifting a sum of a P-tap filter using values of said first reference block.

4. The method according to claim 2, wherein in an instance in which said second motion vector points to an integer sample, said second prediction is obtained by shifting values of said second reference block to the left.

5. The method according to claim 1, wherein said decreasing said precision of said combined prediction by shifting bits of the combined prediction to the right, further comprises:

inserting a rounding offset to the combined prediction before said decreasing.

6. The method according to claim 1, wherein the first precision indicates a number of bits needed to represent the values of the pixels, and the second precision indicates the number of bits needed to represent values of said first prediction and values of said second prediction.

7. An apparatus for encoding a block of pixels, the apparatus comprising:

at least one processor and at least one memory including computer program code, the at least one memory and computer program code configured to, with the at least one processor, cause the apparatus to:

determine, for a current block, a first reference block based on a first motion vector and a second reference block based on a second motion vector, wherein the

22

pixels of the current block, the first reference block, and the second reference block have values with a first precision;

use said first reference block to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference block to obtain a second prediction, said second prediction having the second precision;

obtain a combined prediction based at least partly upon said first prediction and said second prediction;

decrease a precision of said combined prediction by shifting bits of the combined prediction to the right; and encode residual data in a bitstream, wherein the residual data is determined based upon a difference between the combined prediction and the block of pixels.

8. The apparatus according to claim 7, wherein in an instance in which said first motion vector points to a subpixel, said first prediction is obtained by interpolation using pixel values of said first reference block.

9. The apparatus according to claim 8, wherein said first prediction is obtained by interpolation using values of said first reference block by:

right shifting a sum of a P-tap filter using values of said first reference block.

10. The apparatus according to claim 8, wherein in an instance in which said second motion vector points to an integer sample, said second prediction is obtained by shifting values of said second reference block to the left.

11. The apparatus according to claim 7, wherein the at least one memory and computer code are configured to cause the apparatus to decrease said precision of said combined prediction by shifting bits of the combined prediction to the right, by:

inserting a rounding offset to the combined prediction before said decreasing.

12. The apparatus according to claim 7, wherein the first precision indicates a number of bits needed to represent the values of the pixels, and the second precision indicates the number of bits needed to represent values of said first prediction and values of said second prediction.

13. A computer program product for encoding a block of pixels, the computer program product comprising at least one non-transitory computer readable storage medium having computer executable program code portions stored therein, the computer executable program code portions comprising program code instructions configured to:

determine, for a current block, a first reference block based on a first motion vector and a second reference block based on a second motion vector, wherein the pixels of the current block, the first reference block, and the second reference block have values with a first precision;

use said first reference block to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference block to obtain a second prediction, said second prediction having the second precision;

obtain a combined prediction based at least partly upon said first prediction and said second prediction;

decrease a precision of said combined prediction by shifting bits of the combined prediction to the right; and encode residual data in a bitstream, wherein the residual data is determined based upon a difference between the combined prediction and the block of pixels.

23

14. The computer program product according to claim 13, wherein in an instance in which said first motion vector points to a subpixel, said first prediction is obtained by interpolation using pixel values of said first reference block.

15. The computer program product according to claim 14, wherein said first prediction is obtained by interpolation using values of said first reference block by:

right shifting a sum of a P-tap filter using values of said first reference block.

16. The computer program product according to claim 14, wherein in an instance in which said second motion vector points to an integer sample, said second prediction is obtained by shifting values of said second reference block to the left.

17. The computer program product according to claim 13, wherein the program code instructions configured to decrease said precision of said combined prediction by shifting bits of the combined prediction to the right, further comprise program code instructions configured to:

insert a rounding offset to the combined prediction before said decreasing.

18. The computer program product according to claim 13, wherein the first precision indicates a number of bits needed to represent the values of the pixels, and the second precision indicates the number of bits needed to represent values of said first prediction and values of said second prediction.

19. A method for decoding a block of pixels, the method comprising:

determining, for a current block, a first reference block based on a first motion vector and a second reference block based on a second motion vector, wherein the pixels of the current block, the first reference block, and the second reference block have values with a first precision;

using said first reference block to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

using said second reference block to obtain a second prediction, said second prediction having the second precision;

obtaining a combined prediction based at least partly upon said first prediction and said second prediction;

decreasing a precision of said combined prediction by shifting bits of the combined prediction to the right; and reconstructing the block of pixels based on the combined prediction.

20. The method according to claim 19, wherein in an instance in which said first motion vector points to a subpixel, said first prediction is obtained by interpolation using pixel values of said first reference block.

21. The method according to claim 20, wherein said first prediction is obtained by interpolation using values of said first reference block by:

right shifting a sum of a P-tap filter using values of said first reference block.

22. The method according to claim 20, wherein in an instance in which said second motion vector points to an integer sample, said second prediction is obtained by shifting values of said second reference block to the left.

23. The method according to claim 19, wherein said decreasing said precision of said combined prediction by shifting bits of the combined prediction to the right, further comprises:

inserting a rounding offset to the combined prediction before said decreasing.

24. The method according to claim 19, wherein the first precision indicates a number of bits needed to represent the

24

values of the pixels, and the second precision indicates the number of bits needed to represent values of said first prediction and values of said second prediction.

25. An apparatus for decoding a block of pixels, the apparatus comprising:

at least one processor and at least one memory including computer program code, the at least one memory and computer program code configured to, with the at least one processor, cause the apparatus to:

determine, for a current block, a first reference block based on a first motion vector and a second reference block based on a second motion vector, wherein the pixels of the current block, the first reference block, and the second reference block have values with a first precision;

use said first reference block to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

use said second reference block to obtain a second prediction, said second prediction having the second precision;

obtain a combined prediction based at least partly upon said first prediction and said second prediction;

decrease a precision of said combined prediction by shifting bits of the combined prediction to the right; and reconstruct the block of pixels based on the combined prediction.

26. The apparatus according to claim 25, wherein in an instance in which said first motion vector points to a subpixel, said first prediction is obtained by interpolation using pixel values of said first reference block.

27. The apparatus according to claim 26, wherein said first prediction is obtained by interpolation using values of said first reference block by:

right shifting a sum of a P-tap filter using values of said first reference block.

28. The apparatus according to claim 26, wherein in an instance in which said second motion vector points to an integer sample, said second prediction is obtained by shifting values of said second reference block to the left.

29. The apparatus according to claim 25, wherein the at least one memory and computer code are configured to cause the apparatus to decrease said precision of said combined prediction by shifting bits of the combined prediction to the right, by:

inserting a rounding offset to the combined prediction before said decreasing.

30. The apparatus according to claim 25, wherein the first precision indicates a number of bits needed to represent the values of the pixels, and the second precision indicates the number of bits needed to represent values of said first prediction and values of said second prediction.

31. A computer program product for decoding a block of pixels, the computer program product comprising at least one non-transitory computer readable storage medium having computer executable program code portions stored therein, the computer executable program code portions comprising program code instructions configured to:

determine, for a current block, a first reference block based on a first motion vector and a second reference block based on a second motion vector, wherein the pixels of the current block, the first reference block, and the second reference block have values with a first precision;

use said first reference block to obtain a first prediction, said first prediction having a second precision, which is higher than said first precision;

25

use said second reference block to obtain a second prediction, said second prediction having the second precision;

obtain a combined prediction based at least partly upon said first prediction and said second prediction;

decrease a precision of said combined prediction by shifting bits of the combined prediction to the right; and reconstruct the block of pixels based on the combined prediction.

32. The computer program product according to claim **31**, wherein in an instance in which said first motion vector points to a subpixel, said first prediction is obtained by interpolation using pixel values of said first reference block.

33. The computer program product according to claim **32**, wherein said first prediction is obtained by interpolation using values of said first reference block by:

right shifting a sum of a P-tap filter using values of said first reference block.

26

34. The computer program product according to claim **32**, wherein in an instance in which said second motion vector points to an integer sample, said second prediction is obtained by shifting values of said second reference block to the left.

35. The computer program product according to claim **31**, wherein the program code instructions configured to decrease said precision of said combined prediction by shifting bits of the combined prediction to the right, further comprise program code instructions configured to:

insert a rounding offset to the combined prediction before said decreasing.

36. The computer program product according to claim **31**, wherein the first precision indicates a number of bits needed to represent the values of the pixels, and the second precision indicates the number of bits needed to represent values of said first prediction and values of said second prediction.

(57) **ABSTRACT**

An approach is provided for providing an ordering metric for a multi-dimensional contextual query. An ordering platform determines a multi-dimensional query associated with at least one user device, wherein the multi-dimensional query specifies, at least in part, one or more personas, one or more contexts, or a combination thereof associated with the at least one user device. The ordering platform further causes, at least in part, an execution of the multi-dimensional query on at least one context-sensitive database to generate one or more results. The ordering platform further determines at least one ordering metric for the one or more results based, at least in part, on one or more user contextual attributes of the at least one user device.

METHOD AND APPARATUS FOR PROVIDING AN ORDERING METRIC FOR A MULTI-DIMENSIONAL CONTEXTUAL QUERY

BACKGROUND

Service providers and device manufacturers (e.g., wireless, cellular, etc.) are continually challenged to deliver value and convenience to consumers by, for example, providing compelling network services and relevant content. Often, such network and content services rely on the context of the users accessing the network services or the devices by which the users access the network services. Determining the context becomes inadequate when multiple contexts and/or multiple users' actions need to be analyzed over a period of time—particularly when the context is determined in conjunction with a mobile device that has limited processing power and/or bandwidth. However, there still exists a need to have rich, accurate datasets that span different context-aware situations to allow applications that utilize the datasets to be useful for multiple contexts and/or multiple users and provide access to such datasets to mobile devices in a practical manner. As such, device manufacturers and service providers face significant technical challenges to providing rich, situational-aware, context-sensitive datasets in a mobile environment.

SOME EXAMPLE EMBODIMENTS

Therefore, there is a need for an approach for providing an ordering metric for a multi-dimensional contextual query to provide context-aware querying, retrieval and presentation of results on, for example, a mobile interface.

According to one embodiment, a method comprises determining a multi-dimensional query associated with at least one user device, wherein the multi-dimensional query specifies, at least in part, one or more personas, one or more contexts, or a combination thereof associated with the at least one user device. The method also comprises causing, at least in part, an execution of the multi-dimensional query on at least one context-sensitive database to generate one or more results. The method further comprises determining at least one ordering metric for the one or more results based, at least in part, on one or more user contextual attributes of the at least one user device.

According to another embodiment, an apparatus comprises at least one processor, and at least one memory including computer program code for one or more computer programs, the at least one memory and the computer program code configured to, with the at least one processor, cause, at least in part, the apparatus to determine a multi-dimensional query associated with at least one user device, wherein the multi-dimensional query specifies, at least in part, one or more personas, one or more contexts, or a combination thereof associated with the at least one user device. The apparatus is also caused, at least in part, to execute the multi-dimensional query on at least one context-sensitive database to generate one or more results. The apparatus is further caused to determine at least one ordering metric for the one or more results based, at least in part, on one or more user contextual attributes of the at least one user device.

According to another embodiment, a computer-readable storage medium carries one or more sequences of one or more instructions which, when executed by one or more processors, cause, at least in part, an apparatus to determine a multi-dimensional query associated with at least one user device, wherein the multi-dimensional query specifies, at least in

2

part, one or more personas, one or more contexts, or a combination thereof associated with the at least one user device. The apparatus is also caused, at least in part, to execute the multi-dimensional query on at least one context-sensitive database to generate one or more results. The apparatus is further caused to determine at least one ordering metric for the one or more results based, at least in part, on one or more user contextual attributes of the at least one user device.

According to another embodiment, an apparatus comprises means for determining a multi-dimensional query associated with at least one user device, wherein the multi-dimensional query specifies, at least in part, one or more personas, one or more contexts, or a combination thereof associated with the at least one user device. The apparatus also comprises means for causing, at least in part, an execution of the multi-dimensional query on at least one context-sensitive database to generate one or more results. The apparatus further comprises means for determining at least one ordering metric for the one or more results based, at least in part, on one or more user contextual attributes of the at least one user device.

In addition, for various example embodiments of the invention, the following is applicable: a method comprising facilitating a processing of and/or processing (1) data and/or (2) information and/or (3) at least one signal, the (1) data and/or (2) information and/or (3) at least one signal based, at least in part, on (or derived at least in part from) any one or any combination of methods (or processes) disclosed in this application as relevant to any embodiment of the invention.

For various example embodiments of the invention, the following is also applicable: a method comprising facilitating access to at least one interface configured to allow access to at least one service, the at least one service configured to perform any one or any combination of network or service provider methods (or processes) disclosed in this application.

For various example embodiments of the invention, the following is also applicable: a method comprising facilitating creating and/or facilitating modifying (1) at least one device user interface element and/or (2) at least one device user interface functionality, the (1) at least one device user interface element and/or (2) at least one device user interface functionality based, at least in part, on data and/or information resulting from one or any combination of methods or processes disclosed in this application as relevant to any embodiment of the invention, and/or at least one signal resulting from one or any combination of methods (or processes) disclosed in this application as relevant to any embodiment of the invention.

For various example embodiments of the invention, the following is also applicable: a method comprising creating and/or modifying (1) at least one device user interface element and/or (2) at least one device user interface functionality, the (1) at least one device user interface element and/or (2) at least one device user interface functionality based at least in part on data and/or information resulting from one or any combination of methods (or processes) disclosed in this application as relevant to any embodiment of the invention, and/or at least one signal resulting from one or any combination of methods (or processes) disclosed in this application as relevant to any embodiment of the invention.

In various example embodiments, the methods (or processes) can be accomplished on the service provider side or on the mobile device side or in any shared way between service provider and mobile device with actions being performed on both sides.

For various example embodiments, the following is applicable: An apparatus comprising means for performing the method of any of the claims.

3

Still other aspects, features, and advantages of the invention are readily apparent from the following detailed description, simply by illustrating a number of particular embodiments and implementations, including the best mode contemplated for carrying out the invention. The invention is also capable of other and different embodiments, and its several details can be modified in various obvious respects, all without departing from the spirit and scope of the invention. Accordingly, the drawings and description are to be regarded as illustrative in nature, and not as restrictive.

BRIEF DESCRIPTION OF THE DRAWINGS

The embodiments of the invention are illustrated by way of example, and not by way of limitation, in the figures of the accompanying drawings:

FIG. 1 is a diagram of a system capable of providing an ordering metric for a multi-dimensional contextual query, according to one embodiment;

FIG. 2 is a diagram of the components of an ordering platform, according to one embodiment;

FIG. 3 is a flowchart of a process for providing an ordering metric for a multi-dimensional contextual query, according to one embodiment;

FIGS. 4A-4E are diagrams of user interfaces utilized in the process of FIG. 3, according to various embodiments;

FIG. 5 is a diagram of hardware that can be used to implement an embodiment of the invention;

FIG. 6 is a diagram of a chip set that can be used to implement an embodiment of the invention; and

FIG. 7 is a diagram of a mobile terminal (e.g., handset) that can be used to implement an embodiment of the invention.

DESCRIPTION OF SOME EMBODIMENTS

Examples of a method, apparatus, and computer program for providing an ordering metric for a multi-dimensional contextual query are disclosed. In the following description, for the purposes of explanation, numerous specific details are set forth in order to provide a thorough understanding of the embodiments of the invention. It is apparent, however, to one skilled in the art that the embodiments of the invention may be practiced without these specific details or with an equivalent arrangement. In other instances, well-known structures and devices are shown in block diagram form in order to avoid unnecessarily obscuring the embodiments of the invention.

Although various embodiments are described with respect to context-aware databases storing points of interest, it is contemplated that the approach described herein may be used with other context-aware databases storing any type of contextually based information.

FIG. 1 is a diagram of a system capable of providing an ordering metric for a multi-dimensional contextual query, according to one embodiment. As discussed above, services and/or content provided over a network to users' devices often rely on the current context of the users and/or the devices. When multiple contexts and/or multiple users' actions need to be analyzed over a period of time, adapting the applications to use the contexts and/or actions becomes inadequate. Although situation awareness can correlate specific contexts and user actions to specific contextual situations, using such situation awareness has not been incorporated into context-aware databases. Thus, there still exists a need to have rich, accurate datasets that span different context-aware situations to allow applications that utilize the datasets to be useful for multiple contexts and/or multiple users.

4

To address this problem, a system 100 of FIG. 1 introduces the capability to enrich and enhance situational-aware, context-sensitive databases using mechanisms on, for example, a mobile device. The system 100 also has the framework for allowing the mobile user to provide additional information concerning relevant attributes for a data entity in a context-aware database. The system 100 also introduces context-based attribute ordering in the interface of, for example, a mobile device to provide more fluid and less intensive context-aware querying, retrieval and presentation of contextual attributes of objects stored in databases.

As shown in FIG. 1, the system 100 comprises user equipment (UE) 101a-101n (collectively referred to as UE 101) having connectivity to an ordering platform 103 (discussed in detail below) via a communication network 105. The UE 101 include one or more executable applications 111a-111n (collectively referred to as applications 111) that include, for example, one or more mapping applications, messaging applications, calendar applications, context applications, sensor applications, etc. In communication with the UE 101 (e.g., within the UE 101, outside the UE 101) are one or more sensors 117a-117n (collectively referred to as sensors 117) that acquire information regarding the context of the user and/or the UE 101. The sensors 117 can collect any type of information depending on the type of sensor. For example, the sensors 117 can constitute accelerometers, gyroscopes, brightness sensors, moisture sensors, etc. that collect information regarding acceleration, light and water vapor of the UE 101 and the surrounding environment.

In communication with the ordering platform 103 and the UE 101 via the communication network 105 are databases 115a-115n (collectively referred to as databases 115). The databases 115 can be 2-dimensional, relational databases or multi-dimensional (e.g., 3-dimensional, N-dimensional, etc.) databases that are organized into hierarchies that specify an aggregation level and granularity of viewing data.

The databases store objects and information concerning the objects, such as object contextual attributes. The object contextual attributes correspond to the context of the objects, such as, for example, the geographic location of the objects (e.g., address, city, country, etc.), the type of object (e.g., restaurants, schools, parks, and playgrounds), and all other possible types of contextual information related to the objects. By way of example, for an object such as a park, the additional contextual attributes can include whether the park has a playground, whether the park has restrooms, whether the restrooms are clean, whether the park has food concessions, whether the food concessions have a wide range of choices, whether the park has a parking lot or street parking, whether access to the park is free, etc. Each one of these contextual attributes can be further defined by the accuracy, the precision and the resolution of the contextual attributes. For example, the contextual attributes regarding whether the restrooms are clean and/or whether the food concessions have a wide range of choices can have additional attributes indicating the accuracy, the precision and the resolution of the cleanliness of the concessions or the range of choices.

Attributes representing the accuracy, the precision and the resolution can be provided by the provider of the system 100, by the users of the system 100, or a combination thereof. For example, initially the values can be provided by the provider of the system 100 and can be modified, updated, or removed by the users of the system 100. The system 100 can also combine attributes of any one or more of the accuracy, the precision and the resolution into one, singular attribute. For instance, if the information about the cleanliness of the restrooms is both accurate and precise, a single attribute may

5

correspond to “very clean.” If the information about the cleanliness is accurate but not precise, the attribute may correspond to a range, such as “not clean-clean.” In other instances, if the information regarding the cleanliness of the restroom is based on parts of the restroom, the system **100** may indicate the resolution of the information by providing an overall attribute of the cleanliness of the restroom, and also provide discrete attributes for the cleanliness of, for example, the sink, the toilet, the towels etc. within the restroom.

For multi-dimensional databases, each dimension is defined over a dimensional schema, which is a set of dimensional attributes. By way of example, one multidimensional schema can be user preferences attributes. The dimensional attributes of user preferences are, for example, users, location based preferences, context based preferences, behavior based preferences, etc. In this example, the user dimensional attribute is terminal and belongs to the first category level, the location based preferences belongs to the second category level, the context based preferences belongs to the third category level, the behavior based preferences belongs to the fourth category level, etc. By way of further example, each of these dimensional attributes can have further nested multi-dimensional attributes. For example, the location based preferences can include current location based preferences, nearby location based preferences, far location based preferences, etc. where each of these specific location based preferences are representative of a smaller granularity of the location.

The system **100** also includes a service platform **109** that provides one or more services **107a-107n** (collectively known as services **107**) to one or more users and/or user devices. The services **107** can include, for example, location based services, mapping information services, social networking services, etc. In one embodiment, the service platform **109** includes a service **107b** that can convert a 2-dimensional, relational database into a multi-dimensional database for use with the multi-dimensional query of the system **100** according to well-known conversion techniques.

Also included within the system **100** is one or more content providers **113a-113n** (collectively referred to as content providers **113**) that can provide content to one or more services **107** of the service platform **109**, one or more UE **101**, one or more databases **115** and/or the ordering platform **103**. By way of example, as the information regarding the objects stored in the databases **115** changes, the content providers **113** can update the information within the databases. When new objects are created or removed, such as when a new point of interest is created or a new point of interest is closed, the content providers **113** can update the new information within the databases **115**.

By way of example, the communication network **105** of the system **100** includes one or more networks such as a data network, a wireless network, a telephony network, or any combination thereof. It is contemplated that the data network may be any local area network (LAN), metropolitan area network (MAN), wide area network (WAN), a public data network (e.g., the Internet), short range wireless network, or any other suitable packet-switched network, such as a commercially owned, proprietary packet-switched network, e.g., a proprietary cable or fiber-optic network, and the like, or any combination thereof. In addition, the wireless network may be, for example, a cellular network and may employ various technologies including enhanced data rates for global evolution (EDGE), general packet radio service (GPRS), global system for mobile communications (GSM), Internet protocol multimedia subsystem (IMS), universal mobile telecommunications system (UMTS), etc., as well as any other suitable

6

wireless medium, e.g., worldwide interoperability for microwave access (WiMAX), Long Term Evolution (LTE) networks, code division multiple access (CDMA), wideband code division multiple access (WCDMA), wireless fidelity (WiFi), wireless LAN (WLAN), Bluetooth®, Internet Protocol (IP) data casting, satellite, mobile ad-hoc network (MANET), and the like, or any combination thereof.

The UE **101** is any type of mobile terminal, fixed terminal, or portable terminal including a mobile handset, station, unit, device, multimedia computer, multimedia tablet, Internet node, communicator, desktop computer, laptop computer, notebook computer, netbook computer, tablet computer, personal communication system (PCS) device, personal navigation device, personal digital assistants (PDAs), audio/video player, digital camera/camcorder, positioning device, television receiver, radio broadcast receiver, electronic book device, game device, or any combination thereof, including the accessories and peripherals of these devices, or any combination thereof. It is also contemplated that the UE **101** can support any type of interface to the user (such as “wearable” circuitry, etc.).

By way of example, the UE **101**, the ordering platform **103**, the service platform **109**, the content providers **113** and the databases **115** communicate with each other and other components of the communication network **105** using well known, new and/or still developing protocols. In this context, a protocol includes a set of rules defining how the network nodes within the communication network **105** interact with each other based on information sent over the communication links. The protocols are effective at different layers of operation within each node, from generating and receiving physical signals of various types, to selecting a link for transferring those signals, to the format of information indicated by those signals, to identifying which software application executing on a computer system sends or receives the information. The conceptually different layers of protocols for exchanging information over a network are described in the Open Systems Interconnection (OSI) Reference Model.

Communications between the network nodes are typically effected by exchanging discrete packets of data. Each packet typically comprises (1) header information associated with a particular protocol, and (2) payload information that follows the header information and contains information that may be processed independently of that particular protocol. In some protocols, the packet includes (3) trailer information following the payload and indicating the end of the payload information. The header includes information such as the source of the packet, its destination, the length of the payload, and other properties used by the protocol. Often, the data in the payload for the particular protocol includes a header and payload for a different protocol associated with a different, higher layer of the OSI Reference Model. The header for a particular protocol typically indicates a type for the next protocol contained in its payload. The higher layer protocol is said to be encapsulated in the lower layer protocol. The headers included in a packet traversing multiple heterogeneous networks, such as the Internet, typically include a physical (layer 1) header, a data-link (layer 2) header, an internetwork (layer 3) header and a transport (layer 4) header, and various application (layer 5, layer 6 and layer 7) headers as defined by the OSI Reference Model.

FIG. 2 is a diagram of the components of the ordering platform **103**, according to one embodiment. By way of example, the ordering platform **103** includes one or more components for providing an ordering metric for a multi-dimensional contextual query. It is contemplated that the functions of these components may be combined in one or

more components or performed by other components of equivalent functionality. For example, the functions of these components may be embodied in one or more applications 111 executed on a UE 101. Alternatively, the functions of these components can be embodied in one or more modules of the UE 101, or one or more services 107 on the service platform 109.

In this embodiment, the ordering platform 103 includes a persona module 201, a context module 203, a query module 205, an ordering metric module 207, an analyzer module 209, and a user interface module 211.

The persona module 201 determines one or more personas associated with a user of a UE 101 and/or a UE 101. The persona module 201 determines the one or more personas by, for example, a user or users of the UE 101 entering the information regarding the personas.

The personas represent the possible different combinations of users that can be associated with a specific UE 101. By way of example, a persona can represent the members of a family that are associated with the UE 101. The persona can also represent the members of a group of friends that are associated with the UE 101. The personas allow for the creation of situations associated with the UE 101 that correlate to user contextual attributes that form the multi-dimensional queries, in addition to, for example, context information, to generate a list of results from one or more databases 115 that can later be ordered according to an ordering metric.

In one embodiment, when a UE 101 first interfaces with the ordering platform 103, the persona module 201 determines a complete persona associated with the UE 101. By way of example, the complete persona includes representations of the type (e.g., gender, age group, disability, relationships, etc.) and quantity of the users that could possibly be associated with the UE 101. Such examples include one male parent, one female parent, and two infant daughters; one female parent, one teenage boy, and one infant boy; one disabled friend and a non-disabled friend, etc. The complete persona allows the ordering platform 103 to determine all possible personas that could be associated with the UE 101 based on the possible users associated with the UE 101. Thus, the complete persona allows the ordering platform 103 to determine all of the possible user contextual attributes that could be associated with the UE 101 based on the possible users associated with the UE 101.

In one embodiment, the persona module 201 determines one or more personas associated with users of a UE 101 at the time of querying and/or ordering of the one or more results of a multi-dimensional query. The persona module 201 determines the specific users that are associated with the UE 101, and, therefore, associated with the query and/or the ordering metric, and creates the multi-dimensional query based, at least in part, on the user contextual attributes associated with the persona. By way of example, certain user contextual attributes are associated with male parents, female parents, non-parent adults, teenagers, young children, infants, friends, disabled individuals, non-disabled individuals, etc. By indicating the number and type (e.g., gender, age group, disability, relationships, etc.) of users associated with the UE 101 at the time of the query and/or ordering of the one or more results, the ordering platform 103 automatically generates persona information and associates the persona information with user contextual attributes. By doing so, the persona module 201 allows the ordering platform 103 to have situational awareness over the users that are associated with the UE 101 and who are querying the databases 115.

The context module 203 determines the context associated with the user of the UE 101 and/or the UE 101 that is used to

create the multi-dimensional query and/or used to create the ordering metric. The context may comprise, for example, the current location of the user, a future location of the user based on one or more mapping applications 111 running on the UE 101, a current or future appointment based on one or more calendar applications 111 running on the UE 101, etc. The context module 203 can determine the context from, for example, one or more applications 111 running on the UE 101, one or more modules of the UE 101, one or more sensors 117 associated with the UE 101, one or more services 107 associated with the UE 101, or any combination thereof. The context module 203 can also determine the context associated with the users and/or the UE 101 based on interaction information at a user interface of the UE 101. For example, the UE 101 may include user interfaces that allow the users of the UE 101 to enter context regarding the users and/or the UE 101.

In one embodiment, the context module 203 continuously, periodically, or a combination thereof, determines the context information of the user and/or the UE 101 before and after submitting the multi-dimensional query for creating and updating the ordering metric, as discussed below.

The query module 205 creates the multi-dimensional query based on, for example, one or more of the personas and the context acquired by the persona module 201 and the context module 203. The multi-dimensional query can also be based on, for example, one or more dimensions that are specific by a user of the UE 101.

In one embodiment, one dimension can include a contextual dimension for comparing one or more user contextual attributes to one or more object contextual attributes of one or more objects stored in the databases 115. By way of example, the contextual dimension can represent a normalized value of 0 to 1 that defines the most ideally matched object contextual attribute compared to a user contextual attribute. For example, if the context is location, a value of one is the most preferred location of the user and a value of zero is the least preferred location of the user. Thus, if the user contextual attribute for location is a specific latitude and longitude, or a specific street address, and an object has an object contextual attribute with the same latitude and longitude, or street address, the user contextual attribute and the object contextual attribute would have a normalized relation of one, being the most ideally matched.

In one embodiment, one dimension can include a contextual relation dimension for evaluating one or more relations among the one or more user contextual attributes and the one or more object contextual attributes. The contextual relation dimension specifies weighting information, priority information, or a combination thereof of the one or more user contextual attributes, the one or more object contextual attributes, or a combination thereof. Such relations include, for example, an equivalence relation (Q), a total ordering relation (T), and a partial ordering relation (P). In the case of the equivalence relation Q, the results that comply with the user contextual attributes, the one or more object contextual attributes, or a combination thereof are ordered without any special ordering. In the case of the total ordering relation T, the results are sorted based on the contextual dimension discussed above according to the rank of the user contextual attributes, the one or more object contextual attributes, or a combination thereof. In the case of the partial ordering relation P, the results are sorted based on a partial ordering of the contextual dimension discussed above based on the rank of the user contextual attributes, the one or more object contextual attributes, or a combination thereof.

In one embodiment, one dimension can include an inclusion dimension for determining whether to include respective

ones of the one or more results of the multi-dimensional query in a list presented to the user on the user's device. By way of example, the inclusion dimension determines whether objects that include object contextual attributes that do not conform to the user contextual attributes are included or excluded in a list of objects presented to the user. The inclusion attribute can be, for example, unlisted excluded (X), where the objects that include object contextual attributes that do not conform to the user contextual attributes are excluded from the list, and unlisted included (N), where the objects that include object contextual attributes that do not conform to the user contextual attributes are included in the list but come last. The inclusion dimension can be used, for example, to exclude objects and or object information that is unsupported by a mobile device or that is too large to be transmitted over a network to the mobile device.

The query module 205 also executes the multi-dimensional query on the one of more databases 115.

The ordering metric module 207 creates the ordering metric that is used to order the results of the multi-dimensional query. The ordering metric module 207 determines the ordering metric based, at least in part, on one or more of the personas, one or more contexts, one or more of the user contextual attributes, one or more of the object contextual attributes, and one or more dimensions of the multi-dimensional query. In one embodiment, upon generating a list of results representing objects with corresponding object contextual attributes from the databases 115 based on the multi-dimensional query, the ordering metric module 207 generates an ordering metric to order the objects according to the object contextual attributes in comparison to the one or more of the personas, the one or more contexts, the one or more of the user contextual attributes, and the one or more dimensions of the multi-dimensional query. By way of example, the ordering metric orders the objects according to the object contextual attributes in relation to the user contextual attributes according to the contextual dimension and an equivalence relation Q for the contextual relation dimension. The ordering metric module 207 also continuously, periodically, or a combination thereof, monitors for changes in the one or more of the personas, the one or more contexts, the one or more of the user contextual attributes, the one or more of the object contextual attributes, and the one or more dimensions of the multi-dimensional query to reorder the objects based on a new ordering metric. Thus, by way of example, rather than creating a new multi-dimensional query and executing the multi-dimensional query at the databases 115 every time one of the personas, contexts, user contextual attributes, and/or object contextual attributes changes, the ordering platform rather merely updates the ordering metric and reorders the list of result objects with the corresponding object contextual attributes.

The analyzer module 209 determines the accuracy, the precision, and the resolution of the object contextual attributes stored in the databases 115 for the objects presented as results in response to the multi-dimensional query. The accuracy of the object contextual attributes represents the degree of closeness of the object contextual attribute to the actual (true) value. The precision of the object contextual attributes represents the degree of reproducibility of the measurement of the accuracy. The resolution of the object contextual attributes represents the degree of change that is detected. By way of example, some object contextual attributes are yes or no, such as whether a point of interest includes restrooms, parking, or are handicapped accessible. Such contextual attributes should have high degrees of accuracy and precision because there is only one objective answer

(e.g., either yes or no). However, some object contextual attributes can be represented by a normalized value between 0 and 1, such as whether the restrooms are clean, whether the parking spaces can fit a full-sized automobile, whether a restaurant is family friendly, etc. Thus, the analyzer module 209 determines the accuracy, the precision, and the resolution values stored in the databases 115 corresponding to the objects and the object contextual attributes. In one embodiment, the databases 115 already contain the normalized and/or yes/no attributes corresponding to the object contextual attributes. Thus, the analyzer module 209 simply loads the information from the databases 115 and presents the information to the user along with the objects. In one embodiment, the databases 115 have multiple, raw indications of the accuracy, the precision, and the resolution of the object contextual attributes and the analyzer module 209 determines a normalized value for the raw indications. The analyzer module 209 can handle various types of values, ranging from yes/no, to normalized values, to non-normalized values, such as text string descriptions of the object contextual attributes.

In the case where the analyzer module 209 determines the value, the analyzer module 209 determines the accuracy, the precision, and the resolution of the object contextual attributes based on such values (e.g., yes/no, 0-1) stored in the databases 115 associated with the object contextual attributes. The analyzer module 209 determines the actual values based on a wide range of values according to a weighted sum, a weighted average, or a combination thereof of the actual values stored in the databases 115. The analyzer module 209 also interfaces with the user interface module 211 (discussed below) to present the determined values of the accuracy, the precision, and the resolution of the object contextual attributes to the user when the objects are presented as results of the multi-dimensional query.

The analyzer module 209 also receives information from the user, the user of the UE 101, one or more sensors associated with the UE 101, or a combination thereof to further update the values of the accuracy, the precision, and the resolution of the object contextual attributes. By way of example, if a restroom of a restaurant currently has a value of 0.8 associated with the cleanliness attribute based on two reviews or ratings and a user currently rates the cleanliness according as a 0.4 using the user interface of the UE 101, the analyzer module 209 updates the value of the cleanliness of the restroom as a value of 0.66 at the database 115.

The user interface module 211 provides the user interfaces for interfacing with the ordering platform 103. In one embodiment, where the ordering platform 103 is a separate element of the system 100, the user interface module 211 interfaces with one or more applications 111 running on the UE 101 or one or more hardware modules of the UE 101 to provide the user interface on the UE 101 to interface with the ordering platform 103. In one embodiment, where the functions of the ordering platform 103 are embodied in one or more applications 111 running on the UE 101 or in one or more hardware modules of the UE 101, the user interface module 211 interfaces with one or more other hardware modules of the UE 101 to provide the user interface for manipulating the ordering platform 103.

FIG. 3 is a flowchart of a process 300 for providing an ordering metric for a multi-dimensional contextual query, according to one embodiment. In one embodiment, the ordering platform 103 performs the process 300 and is implemented in, for instance, a chip set including a processor and a memory as shown in FIG. 6.

In step 301, the ordering platform 103 determines one or more personas associated with a device (e.g., the UE 101). As

11

discussed above, the personas include, for example, the quantity and type of users that are associated with a device. By way of example, one device is associated with a family that includes a husband, a wife, and five children. In one embodiment, the persona can further be defined by the gender and age group of the children. For example, the five children may include one adult (e.g., over the age of eighteen) female, one teenage (e.g., the ages of thirteen to seventeen) male, one male child (e.g., the ages of two to twelve), and two infant (e.g., younger than two) females. In one embodiment, there may be no distinction between parents and children. For example, the above family would be represented by seven individuals, including one adult male, two adult females, one teenage male, one child male, and two infant females.

Based on the personas, the ordering platform 103 associates the device with one or more situations that are associated with one or more user contextual attributes and/or contexts associated with the members that comprise the persona. For example, by associating a persona of a device with an infant, the ordering platform 103 can associate the device with situations involving infants and user contextual attributes related to infants, such as whether a restaurant has an infant changing room or table in the restroom, whether a location is infant friendly, etc. By associating a persona of a device with an infant and a mother, the ordering platform can associate the device situations involving an infant and the mother of the infant, such as whether a restaurant allows public breast feeding, whether a restaurant has private seating for mothers with infants, etc. By automatically associated the users and/or the device with the personas and related user contextual attributes, the ordering platform 103 is able to determine and handle a wider range of context information based on situational awareness.

In one embodiment, step 301 is performed each time the device interacts with the ordering platform 103 for providing an ordering metric for ordering results of a multi-dimensional contextual query. For example, a first time a device interacts with the ordering platform 103, the user of the device sets up a persona, which is later deleted after ending the interactions with the ordering platform 103. The second time the user interacts with the ordering platform 103, the user is requested to provide information for the persona representing the individuals associated with the device for that particular query. In one embodiment, step 301 is performed to create a default persona that is used each time a multi-dimensional query is issued for determining results of a context-aware database and providing an ordering metric for ordering the results. When the user of the device desires to receive results for a persona other than the default persona, the user is able to temporarily change the persona to a different persona.

In step 303, the ordering platform 103 determines one or more contexts associated with the user of the device and/or the device. The contexts can be related to or further define user contextual attributes associated with the persona setup in step 301 or can be independent of the persona. For example, the contexts can include the current location of the device, a future location of the device based on an application 111a running on the device (e.g., a navigation application with an active route guidance), the current time, a future time based on an application 111b running on the device (e.g., a calendar application with an active or future appointment), etc. The contexts are acquired from any source within the system 100, such as from one or more applications 111 running on the device, one or more sensors 117 associated with the device, one or more services 107 on the service platform 109, and/or one or more content providers 113.

12

In step 305, the ordering platform 103 creates a multi-dimensional query based on the persona and contexts generated from steps 301 and 303 above. The multi-dimensional contextual query includes the situational information associated with the persona from step 301 and includes the context information acquired in step 303. The multi-dimensional query can be of N dimensions.

As discussed above, one dimension can include a contextual dimension for comparing one or more user contextual attributes to one or more object contextual attributes. Further, one dimension can include a contextual relation dimension for evaluating one or more relations among the one or more user contextual attributes and the one or more object contextual attributes. The contextual relation dimension specifies weighting information, priority information, or a combination thereof of the one or more user contextual attributes, the one or more object contextual attributes, or a combination thereof. One dimension can include an inclusion dimension for determining whether to include respective ones of the one or more results of the multi-dimensional query in a list presented to the user on the user's device. One dimension can include the semantic task that the user is involved in, such as finding a restaurant to eat at with the entire family.

In step 307, the ordering platform 103 executes the multi-dimensional query on at least one context-sensitive database 115a to generate one or more results corresponding to object within the databases 115 with their corresponding object contextual attributes. In step 309, the ordering platform 103 determines at least one ordering metric for ordering the one or more results at the device. As discussed above, the ordering metric can be based on a current persona associated with the device, current context information associated with the device, one or more user contextual attributes, one or more object contextual attributes, and/or the multi-dimensional query. The ordering metric can also be based on interaction information at a user interface of the device according to a user modifying any of the above parameters that can modify the ordering metric. By way of example, the user can interact with the device to change the persona information associate with the users of the device from including an infant to not including an infant. Thus, the ordering metric is then based on a persona that does not include an infant and is able to order the results of the multi-dimensional query differently according to the new persona.

In step 311, the ordering platform 103 orders the results of the query based on the at least one ordering metric. The results are ordered based on the object contextual attributes for each of the objects according to the at least one ordering metric. As discussed above, the at least one ordering metric is based, at least in part, on the current persona by ordering object contextual attributes of the one or more results based on the quantity and type of users associated with the device. By way of example, where the users associated with the device include an infant, the at least one ordering metric is focused towards points of interests associated with infants. The at least one ordering metric is based, at least in part, on the current context associated with the device by ordering the object contextual attributes of the one or more results based on the current context. By way of example, where objects include object contextual attributes concerning hours of operation (e.g., hours a restaurant is open, hours for a sale at a store, hours a park is open), the at least one ordering metric orders the objects according to the object contextual attributes that most closely match the current time or a future time. The at least one ordering metric can also be based, at least in part, on the dimensions of the multi-dimensional query. As discussed above, the dimensions of the multi-dimensional con-

13

textual query can include a contextual dimension for comparing the one or more of user contextual attributes and the one or more object contextual attributes, a contextual relation dimension for evaluating one or more relations among the one or more user contextual attributes and the one or more object contextual attributes, and an inclusion dimension for determining whether to include respective ones of the one or more results in a result list. The multi-dimensional query can also include a dimension including the semantic task that the user is involved in. By way of example, if the user is looking for a particular type of restaurant, the ordering metric can include information regarding the particular type of restaurant to rank objects associated with the particular type of restaurant higher than other restaurants.

In step 313, the ordering platform 103 presents accuracy, precision, and/or resolution information regarding the object contextual attributes of the one or more object results of the query. In one embodiment, the ordering platform 103 presents the accuracy, the precision, and/or the resolution information regarding any number of the results of the one or more results. In one embodiment, the ordering platform 103 presents the accuracy, the precision, and/or the resolution information for only a selected one or more of the results of the query.

As discussed above, the accuracy, the precision, and the resolution of the object contextual attributes are stored in the databases 115. The accuracy, the precision, and the resolution of the object contextual attributes are based on such binary values as yes/no or normalized continuous range values such as between 0 and 1. The ordering platform 103 presents the determined values of the accuracy, the precision, and the resolution of the object contextual attributes to the user when the objects are presented as results of the multi-dimensional query.

In step 315, the ordering platform 103 verifies the accuracy, the precision, and/or the resolution of the information regarding the object contextual attributes based on information inputted from the user. By way of example, a user visiting a restaurant who visits the restroom may wish to leave a review regarding the cleanliness of the restaurant. The ordering platform 103 allows the user to enter values regarding the cleanliness of the restroom, such as yes or no, or a normalized value from 0 to 1 (or 1 to 10, etc.) representing various degrees of cleanliness. The ordering platform 103 also allows the user of the device to enter text string values such as, "The worst restroom I have seen to date" to allow for more specificity regarding the object contextual attribute of cleanliness of the restroom. The ordering platform 103 also allows the user of the device to specify more detailed reviews of, for example, restrooms by reviewing parts of the restroom, such as the sink, the toilet, the towels, the floor, etc. Upon the user entering a review of one or more of the object contextual attributes, the ordering platform 103 updates the accuracy, the precision, and/or the resolution of the object contextual attribute based on, for example, a weighted sum, a weighted average, or any other method to update the information and add to the information stored within the databases 115. Thus, the process 300 allows users to add to the situational-aware, context-sensitive information stored within the databases.

In one embodiment, after step 315, the process 300 proceeds back to step 309 based on an indication that any one of the persona, the context, the user contextual attributes, the object contextual attributes, and/or the dimensions have changed indicating that a new ordering metric is created. In this situation, the new ordering metric newly orders the results of the multi-dimensional query without having to query the databases 115 again. This saves time and resources

14

because the information is already at the mobile device. Alternatively, after step 315, the process 300 proceeds back to step 301 for the entire process to be run again in the event that the user wants to create a new multi-dimensional query and determine a new list of results.

FIGS. 4A-4E are diagrams of user interfaces utilized in the processes of FIG. 3, according to various embodiments. FIG. 4A illustrates a user interface 401a of a device 400 (e.g., a UE 101) based on an initial setup of an application 111a interfacing with the ordering platform 103. As discussed above, the user interface 401a includes inputs 403 that allow a user to indicate, for example, the gender, type and quantity of individuals associated with the device 400 to setup the persona associated with the device. By way of example, the persona associated with the device 400 includes one adult male parent, one adult female parent, an adult female non-parent, one teenage male, one child male, and two infant females. The user interface 401a is illustrated when the user wants update or create a persona.

FIG. 4B illustrates a user interface 401b of an application 111a running on a device 400 interfacing with the ordering platform 103. The user interface 401b includes one or more indicators 405 that allow a user to begin a query to determine, for examples, points of interest that the user may wish to visit. By way of example, the user may select the "EAT" indicator 405 to find points of interest involving places to eat. Upon selecting one of the indicators 405, the user interface indicates for the ordering platform 103 to execute a multi-dimensional query on the databases 115 to generate a list of results (e.g., objects) that correspond to the persona and context of associated with the user and/or the device.

FIG. 4C illustrates the user interface 401c of an application 111a running on a device 400 interfacing with the ordering platform 103 including user contextual attributes 407 (and correspondingly object contextual attributes) associated with the determined persona associated with the device 400 that aid the user in finding relevant points of interest. By way of example, if the persona of the user of the device includes a mother with her infant child, the user contextual attributes associated with, for example, parking, a baby room and clean points of interest are determined as the most relevant contextual attributes the user is interested based on the persona. Scrolling down the list of contextual attributes 407 allows the user to select or de-select other contextual attributes, such as, for example, points of interest that are not pricey, points of interest that are open late, and points of interest that have a kids' menu for modify the user contextual attributes associated with the user and/or the device to generate and/or modify the ordering metric.

FIG. 4D illustrates the user interface 401d of an application 111a running on a device 400 interfacing with the ordering platform 103 illustrating detailed information regarding a selected point of interest. Indicator 409 illustrates the specific information regarding the point of interest, such as the name (e.g., Walker Pizza), address (221 Major St., Chicago, Ill.), and phone number (e.g., 312-555-8754) of the point of interest. Included within indicator 409 is indicator 411 that allows a user of the device 400 to enter a review for the particular point of interest.

FIG. 4E illustrates the user interface 401e of an application 111a running on a device 400 interfacing with the ordering platform 103 illustrating the interface for leaving a review of a particular point of interest. By way of example, the user interface 401e includes indicator 413 that includes the object contextual attributes associated with the particular point of interest. As illustrated, a user of the device 400 is allowed to enter reviews of the point of interest based on the particular

15

object contextual attributes by which the point of interest was selected for presentation to the user. In one embodiment, the user can also enter reviews of the object contextual attributes that were not used in selecting the particular object, such as the noise level of a restaurant. As discussed above, the particular point of interest Walker Pizza was selected because the point of interest had object contextual attributes of parking, a baby room, and cleanliness based on the checkmarks of the contextual attributes **407** illustrated in FIG. **4C**. Indicators **415**, **417** and **419** illustrate exemplary ratings of the point of interest. By way of example, the user of the device **400** can indicate whether an object contextual attribute actually existed based on the inclusion of Y for “yes” or N for “no.” The user of the device **400** can also give a numerical value of the object contextual attribute, such as 1-10 representing highly agree (e.g., 1) and highly disagree (e.g., 10) and the different values there between. In one embodiment, the user can also leave text strings regarding the reviews of the object contextual attributes of the point of interest. Based on the above, the ordering platform **103** enters the information entered by the user at the databases **115** to modify the accuracy, the precision and the resolution of the particular object contextual attribute, thus enriching the datasets at the databases **115**.

The processes described herein for providing an ordering metric of a multi-dimensional contextual query may be advantageously implemented via software, hardware, firmware or a combination of software and/or firmware and/or hardware. For example, the processes described herein, may be advantageously implemented via processor(s), Digital Signal Processing (DSP) chip, an Application Specific Integrated Circuit (ASIC), Field Programmable Gate Arrays (FPGAs), etc. Such exemplary hardware for performing the described functions is detailed below.

FIG. **5** illustrates a computer system **500** upon which an embodiment of the invention may be implemented. Although computer system **500** is depicted with respect to a particular device or equipment, it is contemplated that other devices or equipment (e.g., network elements, servers, etc.) within FIG. **5** can deploy the illustrated hardware and components of system **500**. Computer system **500** is programmed (e.g., via computer program code or instructions) to provide ordering metric of a multi-dimensional contextual query as described herein and includes a communication mechanism such as a bus **510** for passing information between other internal and external components of the computer system **500**. Information (also called data) is represented as a physical expression of a measurable phenomenon, typically electric voltages, but including, in other embodiments, such phenomena as magnetic, electromagnetic, pressure, chemical, biological, molecular, atomic, sub-atomic and quantum interactions. For example, north and south magnetic fields, or a zero and non-zero electric voltage, represent two states (0, 1) of a binary digit (bit). Other phenomena can represent digits of a higher base. A superposition of multiple simultaneous quantum states before measurement represents a quantum bit (qubit). A sequence of one or more digits constitutes digital data that is used to represent a number or code for a character. In some embodiments, information called analog data is represented by a near continuum of measurable values within a particular range. Computer system **500**, or a portion thereof, constitutes a means for performing one or more steps of providing an ordering metric of a multi-dimensional contextual query.

A bus **510** includes one or more parallel conductors of information so that information is transferred quickly among devices coupled to the bus **510**. One or more processors **502** for processing information are coupled with the bus **510**.

16

A processor (or multiple processors) **502** performs a set of operations on information as specified by computer program code related to provide an ordering metric of a multi-dimensional contextual query. The computer program code is a set of instructions or statements providing instructions for the operation of the processor and/or the computer system to perform specified functions. The code, for example, may be written in a computer programming language that is compiled into a native instruction set of the processor. The code may also be written directly using the native instruction set (e.g., machine language). The set of operations include bringing information in from the bus **510** and placing information on the bus **510**. The set of operations also typically include comparing two or more units of information, shifting positions of units of information, and combining two or more units of information, such as by addition or multiplication or logical operations like OR, exclusive OR (XOR), and AND. Each operation of the set of operations that can be performed by the processor is represented to the processor by information called instructions, such as an operation code of one or more digits. A sequence of operations to be executed by the processor **502**, such as a sequence of operation codes, constitute processor instructions, also called computer system instructions or, simply, computer instructions. Processors may be implemented as mechanical, electrical, magnetic, optical, chemical or quantum components, among others, alone or in combination.

Computer system **500** also includes a memory **504** coupled to bus **510**. The memory **504**, such as a random access memory (RAM) or any other dynamic storage device, stores information including processor instructions for providing an ordering metric of a multi-dimensional contextual query. Dynamic memory allows information stored therein to be changed by the computer system **500**. RAM allows a unit of information stored at a location called a memory address to be stored and retrieved independently of information at neighboring addresses. The memory **504** is also used by the processor **502** to store temporary values during execution of processor instructions. The computer system **500** also includes a read only memory (ROM) **506** or any other static storage device coupled to the bus **510** for storing static information, including instructions, that is not changed by the computer system **500**. Some memory is composed of volatile storage that loses the information stored thereon when power is lost. Also coupled to bus **510** is a non-volatile (persistent) storage device **508**, such as a magnetic disk, optical disk or flash card, for storing information, including instructions, that persists even when the computer system **500** is turned off or otherwise loses power.

Information, including instructions for providing an ordering metric of a multi-dimensional contextual query, is provided to the bus **510** for use by the processor from an external input device **512**, such as a keyboard containing alphanumeric keys operated by a human user, a microphone, an Infrared (IR) remote control, a joystick, a game pad, a stylus pen, a touch screen, or a sensor. A sensor detects conditions in its vicinity and transforms those detections into physical expression compatible with the measurable phenomenon used to represent information in computer system **500**. Other external devices coupled to bus **510**, used primarily for interacting with humans, include a display device **514**, such as a cathode ray tube (CRT), a liquid crystal display (LCD), a light emitting diode (LED) display, an organic LED (OLED) display, a plasma screen, or a printer for presenting text or images, and a pointing device **516**, such as a mouse, a trackball, cursor direction keys, or a motion sensor, for controlling a position of a small cursor image presented on the display

514 and issuing commands associated with graphical elements presented on the display **514**. In some embodiments, for example, in embodiments in which the computer system **500** performs all functions automatically without human input, one or more of external input device **512**, display device **514** and pointing device **516** is omitted.

In the illustrated embodiment, special purpose hardware, such as an application specific integrated circuit (ASIC) **520**, is coupled to bus **510**. The special purpose hardware is configured to perform operations not performed by processor **502** quickly enough for special purposes. Examples of ASICs include graphics accelerator cards for generating images for display **514**, cryptographic boards for encrypting and decrypting messages sent over a network, speech recognition, and interfaces to special external devices, such as robotic arms and medical scanning equipment that repeatedly perform some complex sequence of operations that are more efficiently implemented in hardware.

Computer system **500** also includes one or more instances of a communications interface **570** coupled to bus **510**. Communication interface **570** provides a one-way or two-way communication coupling to a variety of external devices that operate with their own processors, such as printers, scanners and external disks. In general the coupling is with a network link **578** that is connected to a local network **580** to which a variety of external devices with their own processors are connected. For example, communication interface **570** may be a parallel port or a serial port or a universal serial bus (USB) port on a personal computer. In some embodiments, communications interface **570** is an integrated services digital network (ISDN) card or a digital subscriber line (DSL) card or a telephone modem that provides an information communication connection to a corresponding type of telephone line. In some embodiments, a communication interface **570** is a cable modem that converts signals on bus **510** into signals for a communication connection over a coaxial cable or into optical signals for a communication connection over a fiber optic cable. As another example, communications interface **570** may be a local area network (LAN) card to provide a data communication connection to a compatible LAN, such as Ethernet. Wireless links may also be implemented. For wireless links, the communications interface **570** sends or receives or both sends and receives electrical, acoustic or electromagnetic signals, including infrared and optical signals, that carry information streams, such as digital data. For example, in wireless handheld devices, such as mobile telephones like cell phones, the communications interface **570** includes a radio band electromagnetic transmitter and receiver called a radio transceiver. In certain embodiments, the communications interface **570** enables connection to the communication network **105** for providing an ordering metric of a multi-dimensional contextual query to the UE **101**.

The term “computer-readable medium” as used herein refers to any medium that participates in providing information to processor **502**, including instructions for execution. Such a medium may take many forms, including, but not limited to computer-readable storage medium (e.g., non-volatile media, volatile media), and transmission media. Non-transitory media, such as non-volatile media, include, for example, optical or magnetic disks, such as storage device **508**. Volatile media include, for example, dynamic memory **504**. Transmission media include, for example, twisted pair cables, coaxial cables, copper wire, fiber optic cables, and carrier waves that travel through space without wires or cables, such as acoustic waves and electromagnetic waves, including radio, optical and infrared waves. Signals include man-made transient variations in amplitude, frequency,

phase, polarization or other physical properties transmitted through the transmission media. Common forms of computer-readable media include, for example, a floppy disk, a flexible disk, hard disk, magnetic tape, any other magnetic medium, a CD-ROM, CDRW, DVD, any other optical medium, punch cards, paper tape, optical mark sheets, any other physical medium with patterns of holes or other optically recognizable indicia, a RAM, a PROM, an EPROM, a FLASH-EPROM, an EEPROM, a flash memory, any other memory chip or cartridge, a carrier wave, or any other medium from which a computer can read. The term computer-readable storage medium is used herein to refer to any computer-readable medium except transmission media.

Logic encoded in one or more tangible media includes one or both of processor instructions on a computer-readable storage media and special purpose hardware, such as ASIC **520**.

Network link **578** typically provides information communication using transmission media through one or more networks to other devices that use or process the information. For example, network link **578** may provide a connection through local network **580** to a host computer **582** or to equipment **584** operated by an Internet Service Provider (ISP). ISP equipment **584** in turn provides data communication services through the public, world-wide packet-switching communication network of networks now commonly referred to as the Internet **590**.

A computer called a server host **592** connected to the Internet hosts a process that provides a service in response to information received over the Internet. For example, server host **592** hosts a process that provides information representing video data for presentation at display **514**. It is contemplated that the components of system **500** can be deployed in various configurations within other computer systems, e.g., host **582** and server **592**.

At least some embodiments of the invention are related to the use of computer system **500** for implementing some or all of the techniques described herein. According to one embodiment of the invention, those techniques are performed by computer system **500** in response to processor **502** executing one or more sequences of one or more processor instructions contained in memory **504**. Such instructions, also called computer instructions, software and program code, may be read into memory **504** from another computer-readable medium such as storage device **508** or network link **578**. Execution of the sequences of instructions contained in memory **504** causes processor **502** to perform one or more of the method steps described herein. In alternative embodiments, hardware, such as ASIC **520**, may be used in place of or in combination with software to implement the invention. Thus, embodiments of the invention are not limited to any specific combination of hardware and software, unless otherwise explicitly stated herein.

The signals transmitted over network link **578** and other networks through communications interface **570**, carry information to and from computer system **500**. Computer system **500** can send and receive information, including program code, through the networks **580**, **590** among others, through network link **578** and communications interface **570**. In an example using the Internet **590**, a server host **592** transmits program code for a particular application, requested by a message sent from computer **500**, through Internet **590**, ISP equipment **584**, local network **580** and communications interface **570**. The received code may be executed by processor **502** as it is received, or may be stored in memory **504** or in storage device **508** or any other non-volatile storage for later

execution, or both. In this manner, computer system **500** may obtain application program code in the form of signals on a carrier wave.

Various forms of computer readable media may be involved in carrying one or more sequence of instructions or data or both to processor **502** for execution. For example, instructions and data may initially be carried on a magnetic disk of a remote computer such as host **582**. The remote computer loads the instructions and data into its dynamic memory and sends the instructions and data over a telephone line using a modem. A modem local to the computer system **500** receives the instructions and data on a telephone line and uses an infra-red transmitter to convert the instructions and data to a signal on an infra-red carrier wave serving as the network link **578**. An infrared detector serving as communications interface **570** receives the instructions and data carried in the infrared signal and places information representing the instructions and data onto bus **510**. Bus **510** carries the information to memory **504** from which processor **502** retrieves and executes the instructions using some of the data sent with the instructions. The instructions and data received in memory **504** may optionally be stored on storage device **508**, either before or after execution by the processor **502**.

FIG. **6** illustrates a chip set or chip **600** upon which an embodiment of the invention may be implemented. Chip set **600** is programmed to provide an ordering metric of a multi-dimensional contextual query as described herein and includes, for instance, the processor and memory components described with respect to FIG. **5** incorporated in one or more physical packages (e.g., chips). By way of example, a physical package includes an arrangement of one or more materials, components, and/or wires on a structural assembly (e.g., a baseboard) to provide one or more characteristics such as physical strength, conservation of size, and/or limitation of electrical interaction. It is contemplated that in certain embodiments the chip set **600** can be implemented in a single chip. It is further contemplated that in certain embodiments the chip set or chip **600** can be implemented as a single "system on a chip." It is further contemplated that in certain embodiments a separate ASIC would not be used, for example, and that all relevant functions as disclosed herein would be performed by a processor or processors. Chip set or chip **600**, or a portion thereof, constitutes a means for performing one or more steps of providing user interface navigation information associated with the availability of functions. Chip set or chip **600**, or a portion thereof, constitutes a means for performing one or more steps of providing an ordering metric of a multi-dimensional contextual query.

In one embodiment, the chip set or chip **600** includes a communication mechanism such as a bus **601** for passing information among the components of the chip set **600**. A processor **603** has connectivity to the bus **601** to execute instructions and process information stored in, for example, a memory **605**. The processor **603** may include one or more processing cores with each core configured to perform independently. A multi-core processor enables multiprocessing within a single physical package. Examples of a multi-core processor include two, four, eight, or greater numbers of processing cores. Alternatively or in addition, the processor **603** may include one or more microprocessors configured in tandem via the bus **601** to enable independent execution of instructions, pipelining, and multithreading. The processor **603** may also be accompanied with one or more specialized components to perform certain processing functions and tasks such as one or more digital signal processors (DSP) **607**, or one or more application-specific integrated circuits (ASIC) **609**. A DSP **607** typically is configured to process real-world

signals (e.g., sound) in real time independently of the processor **603**. Similarly, an ASIC **609** can be configured to perform specialized functions not easily performed by a more general purpose processor. Other specialized components to aid in performing the inventive functions described herein may include one or more field programmable gate arrays (FPGA), one or more controllers, or one or more other special-purpose computer chips.

In one embodiment, the chip set or chip **600** includes merely one or more processors and some software and/or firmware supporting and/or relating to and/or for the one or more processors.

The processor **603** and accompanying components have connectivity to the memory **605** via the bus **601**. The memory **605** includes both dynamic memory (e.g., RAM, magnetic disk, writable optical disk, etc.) and static memory (e.g., ROM, CD-ROM, etc.) for storing executable instructions that when executed perform the inventive steps described herein to provide an ordering metric of a multi-dimensional contextual query. The memory **605** also stores the data associated with or generated by the execution of the inventive steps.

FIG. **7** is a diagram of exemplary components of a mobile terminal (e.g., handset) for communications, which is capable of operating in the system of FIG. **1**, according to one embodiment. In some embodiments, mobile terminal **701**, or a portion thereof, constitutes a means for performing one or more steps of providing an ordering metric of a multi-dimensional contextual query. Generally, a radio receiver is often defined in terms of front-end and back-end characteristics. The front-end of the receiver encompasses all of the Radio Frequency (RF) circuitry whereas the back-end encompasses all of the base-band processing circuitry. As used in this application, the term "circuitry" refers to both: (1) hardware-only implementations (such as implementations in only analog and/or digital circuitry), and (2) to combinations of circuitry and software (and/or firmware) (such as, if applicable to the particular context, to a combination of processor(s), including digital signal processor(s), software, and memory(ies) that work together to cause an apparatus, such as a mobile phone or server, to perform various functions). This definition of "circuitry" applies to all uses of this term in this application, including in any claims. As a further example, as used in this application and if applicable to the particular context, the term "circuitry" would also cover an implementation of merely a processor (or multiple processors) and its (or their) accompanying software/or firmware. The term "circuitry" would also cover if applicable to the particular context, for example, a baseband integrated circuit or applications processor integrated circuit in a mobile phone or a similar integrated circuit in a cellular network device or other network devices.

Pertinent internal components of the telephone include a Main Control Unit (MCU) **703**, a Digital Signal Processor (DSP) **705**, and a receiver/transmitter unit including a microphone gain control unit and a speaker gain control unit. A main display unit **707** provides a display to the user in support of various applications and mobile terminal functions that perform or support the steps of providing an ordering metric of a multi-dimensional contextual query. The display **707** includes display circuitry configured to display at least a portion of a user interface of the mobile terminal (e.g., mobile telephone). Additionally, the display **707** and display circuitry are configured to facilitate user control of at least some functions of the mobile terminal. An audio function circuitry **709** includes a microphone **711** and microphone amplifier that amplifies the speech signal output from the microphone

711. The amplified speech signal output from the microphone 711 is fed to a coder/decoder (CODEC) 713.

A radio section 715 amplifies power and converts frequency in order to communicate with a base station, which is included in a mobile communication system, via antenna 717. The power amplifier (PA) 719 and the transmitter/modulation circuitry are operationally responsive to the MCU 703, with an output from the PA 719 coupled to the duplexer 721 or circulator or antenna switch, as known in the art. The PA 719 also couples to a battery interface and power control unit 720.

In use, a user of mobile terminal 701 speaks into the microphone 711 and his or her voice along with any detected background noise is converted into an analog voltage. The analog voltage is then converted into a digital signal through the Analog to Digital Converter (ADC) 723. The control unit 703 routes the digital signal into the DSP 705 for processing therein, such as speech encoding, channel encoding, encrypting, and interleaving. In one embodiment, the processed voice signals are encoded, by units not separately shown, using a cellular transmission protocol such as enhanced data rates for global evolution (EDGE), general packet radio service (GPRS), global system for mobile communications (GSM), Internet protocol multimedia subsystem (IMS), universal mobile telecommunications system (UMTS), etc., as well as any other suitable wireless medium, e.g., microwave access (WiMAX), Long Term Evolution (LTE) networks, code division multiple access (CDMA), wideband code division multiple access (WCDMA), wireless fidelity (WiFi), satellite, and the like, or any combination thereof.

The encoded signals are then routed to an equalizer 725 for compensation of any frequency-dependent impairments that occur during transmission through the air such as phase and amplitude distortion. After equalizing the bit stream, the modulator 727 combines the signal with a RF signal generated in the RF interface 729. The modulator 727 generates a sine wave by way of frequency or phase modulation. In order to prepare the signal for transmission, an up-converter 731 combines the sine wave output from the modulator 727 with another sine wave generated by a synthesizer 733 to achieve the desired frequency of transmission. The signal is then sent through a PA 719 to increase the signal to an appropriate power level. In practical systems, the PA 719 acts as a variable gain amplifier whose gain is controlled by the DSP 705 from information received from a network base station. The signal is then filtered within the duplexer 721 and optionally sent to an antenna coupler 735 to match impedances to provide maximum power transfer. Finally, the signal is transmitted via antenna 717 to a local base station. An automatic gain control (AGC) can be supplied to control the gain of the final stages of the receiver. The signals may be forwarded from there to a remote telephone which may be another cellular telephone, any other mobile phone or a land-line connected to a Public Switched Telephone Network (PSTN), or other telephony networks.

Voice signals transmitted to the mobile terminal 701 are received via antenna 717 and immediately amplified by a low noise amplifier (LNA) 737. A down-converter 739 lowers the carrier frequency while the demodulator 741 strips away the RF leaving only a digital bit stream. The signal then goes through the equalizer 725 and is processed by the DSP 705. A Digital to Analog Converter (DAC) 743 converts the signal and the resulting output is transmitted to the user through the speaker 745, all under control of a Main Control Unit (MCU) 703 which can be implemented as a Central Processing Unit (CPU).

The MCU 703 receives various signals including input signals from the keyboard 747. The keyboard 747 and/or the

MCU 703 in combination with other user input components (e.g., the microphone 711) comprise a user interface circuitry for managing user input. The MCU 703 runs a user interface software to facilitate user control of at least some functions of the mobile terminal 701 to provide an ordering metric of a multi-dimensional contextual query. The MCU 703 also delivers a display command and a switch command to the display 707 and to the speech output switching controller, respectively. Further, the MCU 703 exchanges information with the DSP 705 and can access an optionally incorporated SIM card 749 and a memory 751. In addition, the MCU 703 executes various control functions required of the terminal. The DSP 705 may, depending upon the implementation, perform any of a variety of conventional digital processing functions on the voice signals. Additionally, DSP 705 determines the background noise level of the local environment from the signals detected by microphone 711 and sets the gain of microphone 711 to a level selected to compensate for the natural tendency of the user of the mobile terminal 701.

The CODEC 713 includes the ADC 723 and DAC 743. The memory 751 stores various data including call incoming tone data and is capable of storing other data including music data received via, e.g., the global Internet. The software module could reside in RAM memory, flash memory, registers, or any other form of writable storage medium known in the art. The memory device 751 may be, but not limited to, a single memory, CD, DVD, ROM, RAM, EEPROM, optical storage, magnetic disk storage, flash memory storage, or any other non-volatile storage medium capable of storing digital data.

An optionally incorporated SIM card 749 carries, for instance, important information, such as the cellular phone number, the carrier supplying service, subscription details, and security information. The SIM card 749 serves primarily to identify the mobile terminal 701 on a radio network. The card 749 also contains a memory for storing a personal telephone number registry, text messages, and user specific mobile terminal settings.

While the invention has been described in connection with a number of embodiments and implementations, the invention is not so limited but covers various obvious modifications and equivalent arrangements, which fall within the purview of the appended claims. Although features of the invention are expressed in certain combinations among the claims, it is contemplated that these features can be arranged in any combination and order.

What is claimed is:

1. A method comprising facilitating a processing of and/or processing (1) data and/or (2) information and/or (3) at least one signal, the (1) data and/or (2) information and/or (3) at least one signal based, at least in part, on the following:

a determination of a multi-dimensional query associated with at least one user device, wherein the multi-dimensional query specifies, at least in part, one or more personas, based, at least in part, on more than one person, associated with the at least one user device;

an execution of the multi-dimensional query on at least one context-sensitive database to generate one or more results; and

a determination of at least one ordering metric for the one or more results based, at least in part, on one or more user contextual attributes of the at least one user device.

2. A method of claim 1, wherein the (1) data and/or (2) information and/or (3) at least one signal are further based, at least in part, on the following:

a determination of one or more object contextual attributes associated with the one or more results,

23

wherein the at least one ordering metric is further based, at least in part, on the one or more object contextual attributes.

3. A method of claim 2, wherein the (1) data and/or (2) information and/or (3) at least one signal are further based, at least in part, on the following:

a determination of an accuracy, a precision, a resolution, or a combination thereof of the one or more object contextual attributes; and

a display of one or more representations of the accuracy, the precision, the resolution, or a combination thereof.

4. A method of claim 3, wherein the (1) data and/or (2) information and/or (3) at least one signal are further based, at least in part, on the following:

a determination of the accuracy, the precision, the resolution, or a combination thereof based, at least in part, on sensor information, survey information, user update information, or a combination thereof.

5. A method of claim 4, wherein the (1) data and/or (2) information and/or (3) at least one signal are further based, at least in part, on the following:

an updating of the one or more object contextual attributes at the at least one context-sensitive database based on the determined accuracy, the determined precision, the determined resolution, or a combination thereof.

6. A method of claim 2, wherein the at least one ordering metric is based, at least in part, on a weighted sum, a weighted average, or a combination thereof of one or more dimensions of the multi-dimensional query.

7. A method of claim 6, wherein the one or more dimensions include, at least in part, (i) a contextual dimension for comparing the one or more user contextual attributes and the one or more object contextual attributes, (ii) a contextual relation dimension for evaluating one or more relations among the one or more user contextual attributes and the one or more object contextual attributes, and (iii) an inclusion dimension for determining whether to include respective ones of the one or more results in a result list.

8. A method of claim 7, wherein the contextual relation dimension specifies weighting information, priority information, or a combination thereof for the one or more user contextual attributes, the one or more object contextual attributes, or combination thereof.

9. A method of claim 1, wherein the multi-dimensional query specifies, at least in part, one or more contexts associated with the at least one user device, and the (1) data and/or (2) information and/or (3) at least one signal are further based, at least in part, on the following:

a processing of the one or more user contextual attributes to select from among the one or more personas, the one or more contexts, or a combination thereof,

wherein the at least one ordering metric is based, at least in part, on the selected one or more personas, the selected one or more contexts, or a combination thereof.

10. A method of claim 1, wherein the (1) data and/or (2) information and/or (3) at least one signal are further based, at least in part, on the following:

a determination of contextual information, interaction information at a user interface of the at least one user device, or a combination thereof associated with the at least one user device; and

a processing of the contextual information, the interaction information, or a combination thereof to determine, at least in part, the one or more user contextual attributes.

24

11. An apparatus comprising:

at least one processor; and

at least one memory including computer program code for one or more programs,

the at least one memory and the computer program code configured to, with the at least one processor, cause the apparatus to perform at least the following,

determine a multi-dimensional query associated with at least one user device, wherein the multi-dimensional query specifies, at least in part, one or more personas, based, at least in part, on more than one person, associated with the at least one user device;

cause, at least in part, an execution of the multi-dimensional query on at least one context-sensitive database to generate one or more results; and

determine at least one ordering metric for the one or more results based, at least in part, on one or more user contextual attributes of the at least one user device.

12. An apparatus of claim 11, wherein the apparatus is further caused to:

determine one or more object contextual attributes associated with the one or more results,

wherein the at least one ordering metric is further based, at least in part, on the one or more object contextual attributes.

13. An apparatus of claim 12, wherein the apparatus is further caused to:

determine an accuracy, a precision, a resolution, or a combination thereof of the one or more object contextual attributes; and

cause, at least in part, a display of one or more representations of the accuracy, the precision, the resolution, or a combination thereof.

14. An apparatus of claim 13, wherein the apparatus is further caused to:

determine the accuracy, the precision, the resolution, or a combination thereof based, at least in part, on sensor information, survey information, user update information, or a combination thereof.

15. An apparatus of claim 14, wherein the apparatus is further caused to:

cause, at least in part, an updating of the one or more object contextual attributes at the at least one context-sensitive database based on the determined accuracy, the determined precision, the determined resolution, or a combination thereof.

16. An apparatus of claim 12, wherein the at least one ordering metric is based, at least in part, on a weighted sum, a weighted average, or a combination thereof of one or more dimensions of the multi-dimensional query.

17. An apparatus of claim 16, wherein the one or more dimensions include, at least in part, (i) a contextual dimension for comparing the one or more user contextual attributes and the one or more object contextual attributes, (ii) a contextual relation dimension for evaluating one or more relations among the one or more user contextual attributes and the one or more object contextual attributes, and (iii) an inclusion dimension for determining whether to include respective ones of the one or more results in a result list.

18. An apparatus of claim 17, wherein the contextual relation dimension specifies weighting information, priority information, or a combination thereof for the one or more user contextual attributes, the one or more object contextual attributes, or combination thereof.

19. An apparatus of claim 11, wherein the multi-dimensional query specifies, at least in part, one or more contexts associated with the at least one user device, and the apparatus is further caused to:

process and/or facilitate a processing of the one or more user contextual attributes to select from among the one or more personas, the one or more contexts, or a combination thereof,

wherein the at least one ordering metric is based, at least in part, on the selected one or more personas, the selected one or more contexts, or a combination thereof.

20. An apparatus of claim 11, wherein the apparatus is further caused to:

determine contextual information, interaction information at a user interface of the at least one user device, or a combination thereof associated with the at least one user device; and

process and/or facilitate a processing of the contextual information, the interaction information, or a combination thereof to determine, at least in part, the one or more user contextual attributes.
